Background. In 2016, the South Korean Integrated Nursing-Care Service, covered by national insurance, was initiated, with a particular focus on cancer-oriented units. Integrated Nursing-Care Service Wards denote facilities wherein nursing professionals deliver holistic care, in the absence of paid informal caregivers (hereafter will be called caregiver). **Aim.** This study, framed within Demerouti's Job Demands-Job Resources Model, aimed to analyze variables influencing nurses' work engagement in Integrated Nursing-Care Service wards. **Methods.** From April to June 2022, 375 participants working at three certified tertiary hospitals operating Integrated Nursing-Care Service wards completed the survey. Of the 400 distributed questionnaires, 375 were used for analysis, resulting in a response rate of 93.75%. The remaining 25 questionnaires were excluded due to insufficient responses. Job demands, job resources, and personal resources were assigned as exogenous variables that predicted burnout and work engagement of nurses, while burnout and work engagement were assigned as endogenous variables. In this model, 32 hypotheses were established, and to verify the hypotheses, the direct effect of each exogenous variable on work engagement and the indirect effect through burnout as a medium were analyzed. **Results.** Burnout partially mediated the impact of exogenous variables on work engagement. The subfactors revealed partial mediation between emotional labor and work engagement, full mediation for satisfaction with the recognition from patients and caregivers, and partial mediation for resilience. **Conclusion.** Emotional labor had the highest impact on nurses' burnout in Integrated Nursing-Care Service wards, followed by resilience and satisfaction with the recognition from patients and caregivers. Nurses' burnout, work environment, emotional labor, work overload, and resilience significantly influenced their work engagement. **Implications for Nursing Management.** The results of this study are useful as basic data for research on intervention programs that reduce burnout and increase nurses' work engagement in Integrated Nursing-Care Service wards.

1. Introduction

Changes in family and social structures, such as population aging, the rise of chronic diseases, and nuclear families, are phenomena that occur in many countries worldwide [1]. In South Korea, the social activities and demands of family members have led to a trend of shifting direct care from family members to paid informal caregivers when patients are hospitalized. Caregivers help patients with their daily activities on behalf of their families or play a role in patient safety under the direction and supervision of nurses [2].

South Korea has a nursing workforce of 8.8 nurses per 1,000 people, which is 1.0 less than the Organization for Economic Co-operation and Development (OECD) average (9.8) [3]. The ratio of patients per nurse in the US is 5.3, while the ratio in South Korea is nearly 16.3 patients per nurse [4], which is still inadequate, and the burden of family caregiving and care costs continues to increase due to the lack of nursing staff and the hiring of private caregivers.

In 2013, the government expanded the nursing staff to include nurses and nursing assistants to provide nursing care to patients who were previously cared for by family members

or private paid caregivers [5]. In 2016, the government renamed the program as the Nursing and Care Integration Service and gradually expanded the initiative to include not only small- and medium-sized hospitals but also general hospitals [6]. The Integrated Nursing-Care Service is a comprehensive nursing care service that provides hospitalized patients with adequate nursing care, even if their guardians are not present, by securing adequate nursing staff, introducing a team care system, and improving the ward environment. In principle, all nursing services provided to hospitalized patients are provided by nurses and nursing assistants in medical institutions, and the system aims to improve the quality of hospitalized medical services and reduce the caregiving burden on guardians. On the patient side, providing Integrated Nursing-Care Service has led to positive changes in quality, including increased satisfaction with the high quality of care, improved intentions to return for care due to better ward environment, and decreased incidence of falls, pressure ulcers, and infections, which are patient safety indicators [7].

On the other hand, in terms of nurses, who are the mainstay of the core workforce, there are also negative aspects, such as the burden of increased workload and emphasis on the importance of nurses' role, as they are required to provide 24-hour care for patients in close proximity without a guardian or caregiver [5]. In addition, there are many cases of job stress leading to burnout among nurses in Integrated Nursing-Care Service wards due to distrust from patients and caregivers who are accustomed to receiving care from family members and caregivers and demands beyond the scope of nursing services [8]. Excessive job stress due to changes in traditional nursing duties and increased responsibilities can lead to negative work attitudes and self-concept, leading to burnout [9].

Nurse burnout negatively affects job satisfaction in the long run and reduces the quality of healthcare services provided by nurses [10]. Therefore, interventions and strategies are needed to decrease burnout and increase work engagement among nurses in Integrated Nursing-Care Service wards. Burnout refers to a state of physical, emotional, and mental exhaustion caused by chronic stress during the workday for members of an organization with frequent contact with others [11]. It can lead to job dissatisfaction and increased errors in nursing care due to formal work performance, which in turn can lead to decreased patient and caregiver satisfaction and nurse turnover [12]. Strengthening nurses' resilience is an important factor that can help them overcome the difficulties in work performance caused by burnout, and improve the quality of care. Resilience, an internal coping resource, is the ability to respond flexibly and adapt to negative factors [12], and individuals with higher levels of resilience may be able to overcome the negative effects of workplace adversity and challenges and consequently experience less burnout [13].

In contrast to burnout, work engagement refers to a positive and fulfilling attitude toward work and motivating the nursing workforce [14]. Individuals with high work engagement have a strong sense of belonging to the organization, engage in their work to seek positive feedback from

supervisors and the organization, and have a strong passion for activities outside of their role. Work engagement also affects nurses' personal resources, such as resilience and self-esteem [15].

Burnout and work engagement in nursing can also be explained by the Job Demands-Resources model (JD-R model), which explains burnout and work engagement from an organizational perspective rather than an individual perspective and divides job-related factors into job demands and job resources. Xanthopoulou et al. [16] extended the JD-R model by adding personal resources to it. Later, Keyko et al. [17] extended the model to develop the Nursing Job Demands-Resources (NJD-R) model applicable to professional nursing practices. According to their findings, work engagement exists in the organizational environment and at the work level, and the positive outcomes of work engagement can improve performance for the organization, increase value for the nurses, and decrease negative outcomes within the healthcare organization. The NJD-R model, derived from this research, suggests opportunities to promote nurses' work engagement, providing a foundational framework for understanding nursing practice, conducting direct nursing research, and guiding practices and policies [17].

Therefore, this study aimed to identify the effects of burnout and work engagement on nurses in Integrated Nursing-Care Service wards and explore ways to decrease burnout and increase work engagement in Integrated Nursing-Care Service wards by identifying factors that affect work engagement through the mediation of burnout and identifying pathways between factors. In this study, burnout was examined as an outcome influenced by various job demands and resources. This perspective is crucial as it allows us to understand how burnout impacts job satisfaction and the quality of healthcare services. By treating burnout as a result, we can better analyze its underlying causes and develop strategies to mitigate its effects on healthcare professionals and the care system as a whole.

2. Materials and Methods

2.1. Design and Sampling. This is a descriptive research study based on the JD-R model (Figure 1). It consists of seven exogenous variables (role conflict and role ambiguity, emotional labor, work overload, professional autonomy, nurses' work environment, satisfaction with the recognition from patients and caregivers, and resilience) and two endogenous variables (burnout and work engagement), with burnout as a parameter. In this context, "burnout as a parameter" means that burnout is used as an intermediary variable that mediates the relationship between the exogenous variables and the endogenous variables. This mediating role allows us to examine how burnout influences the impact of these variables on work engagement. The paths between the variables were hypothesized to be role conflict and role ambiguity, emotional labor, work overload, professional autonomy, nurses' work environment, satisfaction with the recognition from patients and caregivers, resilience affecting burnout and work engagement, and burnout affecting work engagement.

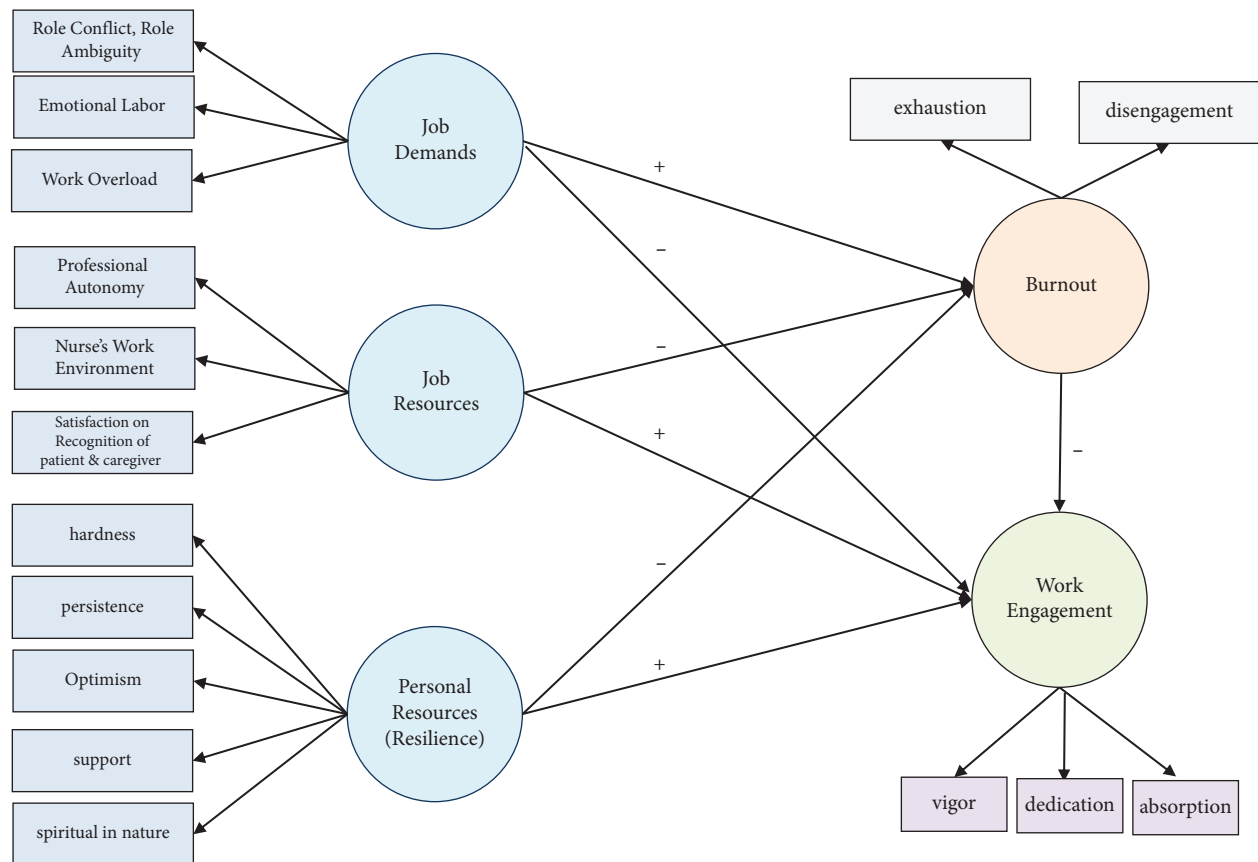

FIGURE 1: The conceptual map of study variables.

2.2. Data Collection. Data were collected from April 27 to June 24, 2022, from nurses with at least 1 year of work experience in three tertiary general hospitals and who experienced similar levels of work intensity in Integrated Nursing-Care Service wards in Incheon and Bucheon, South Korea, and understood the purpose of the study and agreed to participate. After obtaining prior consent from the head of the nursing department of the hospital, the researcher sought cooperation from the head nurse of the ward, explained the purpose of the study, obtained written consent, and administered the questionnaire. To reduce sampling errors in structural equations, a sample size of 200–400 is required, regardless of the size of the model [18]. Accordingly, 400 questionnaires were distributed, and 375 questionnaires were analyzed after excluding those who responded dishonestly.

2.3. Measures. Participant characteristics included age, gender, education, position, clinical experience, experience in Integrated Nursing-Care Service wards, and length of service in Integrated Nursing-Care Service wards.

Job demands included role conflict and role ambiguity, emotional labor, and work overload; job resources were professional autonomy, nurses' work environment, satisfaction with the recognition from patients and caregivers; personal resources were resilience; and endogenous variables were burnout and work engagement.

2.3.1. Job Demands

(1) *Role Conflict and Role Ambiguity.* The questionnaire developed by Rizzo and Lirtzman [19] and adapted by Kim [20] has a total of 10 questions rated on a 5-point Likert scale, with higher scores indicating higher role conflict and role ambiguity. In this study, the reliability of role conflict was Cronbach's α 0.81, and the reliability of role ambiguity was Cronbach's α 0.79.

(2) *Emotional Labor.* Emotional labor refers to the process of managing feelings and expressions to fulfill the emotional requirements of a job [21]. It includes factors such as the frequency of emotional expression, caution in emotional expression, and emotional dissonance, measured by a tool developed by Kim [22] based on the research of Morris and Feldman [21]. The tool comprises a total of nine subfactors, including three questions each on the frequency of emotional expression, caution in emotional expression, and emotional dissonance. Participants rated these subfactors on a 5-point Likert scale, with higher scores indicating elevated levels of emotional labor. The reliability of the tool in this study was assessed using Cronbach's alpha, yielding a value of 0.83.

(3) *Work Overload.* The work overload measure, a component of the Work-Job Demands subscale within the Questionnaire on the Experience and Evaluation of Work

(QEEW) 2.0 tool, was developed by Van Veldhoven et al. [23] and translated by Lim [24]. This measure consists of six questions, and participants rate their responses on a 4-point Likert scale. Higher scores on this scale indicate a greater perception of work overload. The reliability of the tool in this study was assessed using Cronbach's alpha, yielding a value of 0.88.

2.3.2. Job Resources

(1) *Professional Autonomy.* The Professional Autonomy Scale developed by Schutzenhofer [25], adapted by Han [26], and modified by Kim [27] has a total of six questions rated on a 5-point Likert scale, with higher scores indicating higher levels of professional autonomy. The reliability of this study was Cronbach's α 0.76.

(2) *Nurses' Work Environment.* The Korean Work Environment Scales for Clinical Nurses (KWES-CN), developed by Kim et al. [28] and modified and supplemented by Shim [29], have a total of 18 questions rated on a 4-point Likert scale, with higher scores indicating a better nurses' work environment. The reliability of this study was Cronbach's α 0.86.

(3) *Satisfaction with Recognition from Patients and Caregivers.* The Job Satisfaction Tool developed by Paula et al. [30], translated by Han et al. [26], and used by Park [31] and the Volunteer Satisfaction Tool of Choi [32] reorganized, modified, and supplemented by Shim [29] have a total of five questions rated on a 5-point Likert scale, with higher scores indicating higher satisfaction with the recognition from patients and caregivers. The reliability of this study was Cronbach's α 0.87.

2.3.3. Personal Resources

(1) *Resilience.* The Connor–Davidson Resilience Scale (CD-RISC), developed by Connor and Davidson [33] and adapted and validated by Baek [34] as the K-CD-RISC, has a total of 25 questions rated on a 5-point Likert scale, with higher scores indicating higher resilience. CD-RISC indeed provides subscales, measuring resilience through five distinct factors: hardiness, persistence, optimism, support, and spirituality [34]. Each subscale is assessed through specific items on the scale. Hardiness reflects the ability to endure difficult conditions. Persistence indicates the capacity to continue despite adversity. Optimism measures a general positive outlook on life and the future. Support evaluates the perceived availability of social support, and spirituality captures a sense of purpose and faith in something greater. The reliability of this study was Cronbach's α 0.92.

2.3.4. *Burnout.* The Oldenburg Burnout Inventory (OLBI), developed by Demerouti and Nachreiner [35] and translated by Choi [36], has a total of six questions rated on a 5-point Likert scale, with higher scores indicating higher levels of burnout. The reliability of this study was Cronbach's α 0.76.

2.3.5. *Work Engagement.* Work engagement is defined as a positive, fulfilling, work-related state of mind characterized by vigor, dedication, and absorption [37]. It is measured using the Dutch Utrecht Work Engagement Scale (UWES-9). The Dutch Utrecht Work Engagement Scale (UWES-9), developed by Schaufeli et al. [37] and translated by Baek [38], has a total of nine questions rated on a 7-point Likert scale, with higher scores indicating higher work engagement. The reliability of this study was Cronbach's α 0.91.

2.4. *Data Analysis.* Descriptive statistics and Pearson's correlation coefficient analysis were conducted using SPSS 25.0, and the fitness of the hypothetical model, path coefficient, and effect were verified using AMOS 23.0.

To verify the suitability of the model, absolute fit indices (χ^2 , χ^2/df), root mean square residual (RMR), goodness-of-fit index (GFI), adjusted goodness-of-fit index (AGFI), root mean square error of approximation (RMSEA), Tucker–Lewis index (TLI), and comparative fit index (CFI) were used for the analysis.

The significance of the path coefficient of the structural model was verified using the unstandardized coefficient (B), standardized coefficient (β), standard error (SE), and p value, and the explanatory power of the endogenous variables was confirmed using square multiple correlation (SMC).

2.5. *Ethical Considerations.* After obtaining approval from the Institutional Review Board of Gachon University (IRB approval number: 1044396-202201-HR-027-01), written consent was obtained from all the participants, and the study contents were explained to them. The written consent form included information on the purpose of the study, data collection methods, autonomy to participate in or withdraw from the study, confidentiality of information and interests, discomfort, and time required to complete the questionnaire. A self-administered questionnaire was administered to those who voluntarily agreed to participate in writing. All the nurses who participated in the study were offered a small gift as a token of appreciation.

3. Results

3.1. *General Characteristics.* The average age of the nurses was 29.90 years (± 6.32), approximately 95.7% of the total sample was female, and four-fifths of the nurses had a bachelor's degree in nursing. More than 80% of the positions were general nurses, with an average clinical experience of 7.32 (± 6.76) years, 107 (35.7%) had 1–2 years of experience in nursing and Integrated Nursing-Care Service wards, 150 (50.0%) had 3–5 years of experience, and 43 (14.3%) had more than 6 years of experience in nursing and Integrated Nursing-Care Service wards, and the average number of years of experience in nursing and integrated care units was 3.33 (± 1.62) (Table 1).

3.2. *Validation Results of the Research Model.* The proposed structural model proved to be a very good fit with $\chi^2 = 566.031$ ($df = 265$), $\chi^2/df = 2.136$. The GFI was 0.894,

TABLE 1: General characteristics of the participants ($N = 375$).

Characteristics	Category	<i>n</i>	%
Gender	Male	16	4.3
	Female	359	95.7
Age (years)	20–29	247	60.9
	30–39	87	23.2
	40–49	34	9.1
	≥50	7	1.9

	21≤	24	7.3
Experience in Integrated Nursing-Care Service wards (years)	1–<2	107	35.7
	3–<5	150	50.0
	6≤	43	14.3

AGFI was 0.849, TLI was 0.919, CFI was 0.939, RMR was 0.029, and RMSEA was 0.055, showing very high fit (Figure 2).

The variable with the greatest impact on nurses' burnout in Integrated Nursing-Care Service wards was emotional labor, followed by resilience and satisfaction with the recognition from patients and caregivers. Burnout was the most variable influencing nurses' work engagement in Integrated Nursing-Care Service wards, followed by nurses' work environment, emotional labor, work overload, and resilience (Table 2).

3.3. Results of Verification of Significance of Mediating Effect. Regarding the mediating effects, emotional labor, satisfaction with the recognition from patients and caregivers, and resilience had a significant effect on burnout. Regarding work engagement, emotional labor, work overload, and nurses' work environment had a significant effect on work engagement. Moreover, resilience and burnout had a significant effect on work engagement.

The indirect effects' results showed that burnout partially mediated the relationship between emotional labor and work engagement, fully mediated the relationship between satisfaction with the recognition from patients and caregivers and work engagement, and partially mediated the relationship between resilience and work engagement (Table 3).

4. Discussion

This study analyzed the factors affecting nurses' burnout and work engagement based on Xanthopoulou et al.'s [16] extended Job Demands-Job Resources model. The results of the structural model analysis confirmed that job demands, job resources, and personal resources affected burnout and work engagement. In addition, the proposed structural model, based on the upper and lower factors, showed a high degree of fit, confirming its high explanatory power. Based on these findings, we discuss the following points.

4.1. Factors Influencing Nurses' Burnout in Integrated Nursing-Care Service Wards. First, job demands had a positive effect on burnout. In particular, emotional labor had a significant effect on burnout, which is consistent with the findings of Kim et al. [39], Kim [40], and Hyun and Lee [41]. Emotional labor is common in interactive nursing work and can lead to increased burnout. Therefore, intervention programs and educational measures to reduce nurses' emotional labor are needed. Second, job resources of nurses in Integrated Nursing-Care Service wards had a negative effect on burnout. In particular, satisfaction with the recognition from patients and caregivers affected burnout. Patient and guardian recognition is an important variable nationwide related to the expansion of integrated nursing-care services. To improve this situation, publicity programs

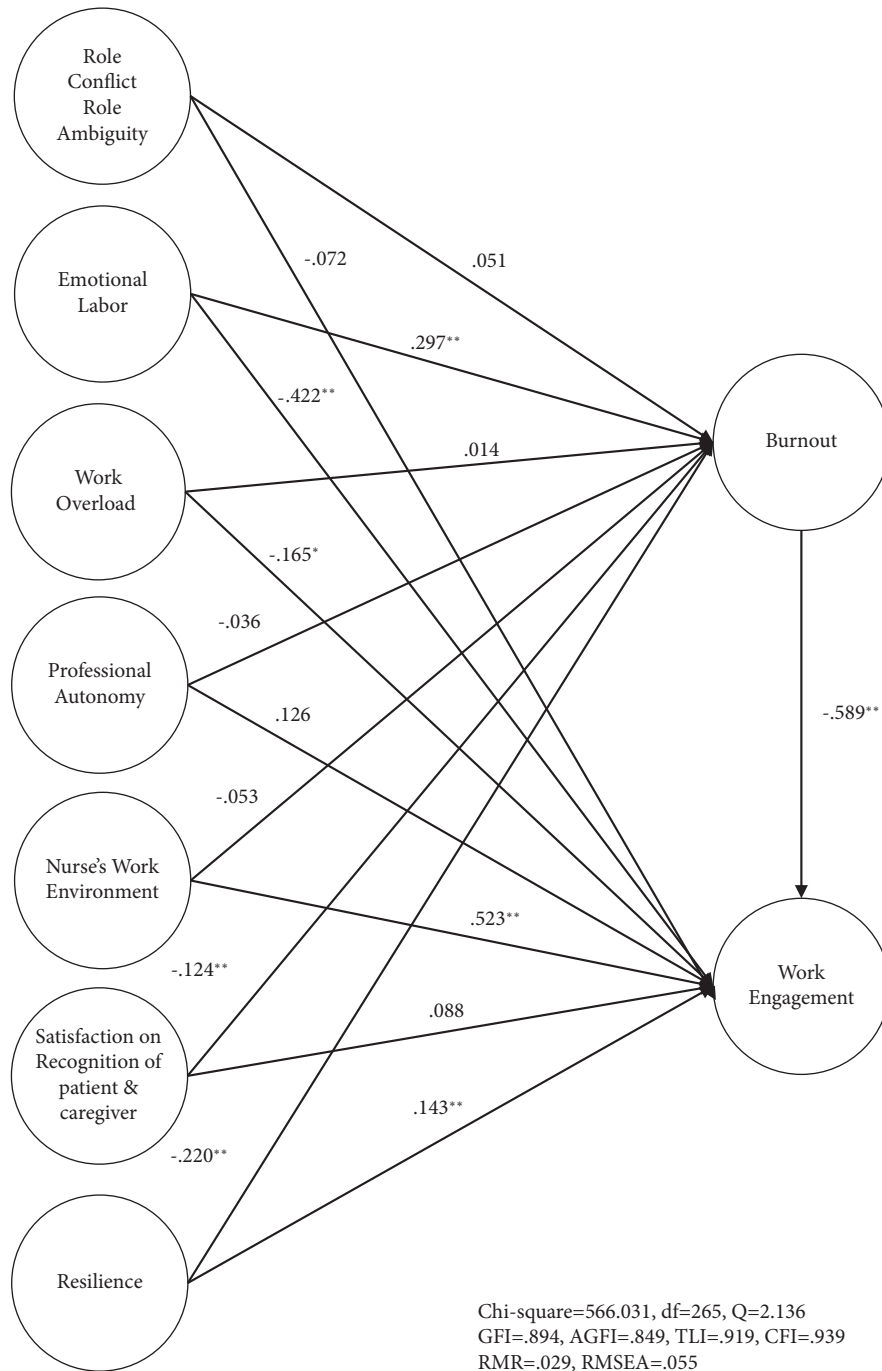

FIGURE 2: Structural equation modeling of the research model. * $p < 0.05$; ** $p < 0.01$.

are needed to increase awareness and provide information about social nursing services. Third, resilience, a personal resource, had a negative effect on burnout, which is consistent with the findings of Kim [42], Yang and Gu [15], and Hyun and Lee [41]. As nurses' resilience is an acquired factor shaped by their personalities and stress management skills, a personal approach and organizational support are needed. It is necessary to develop various programs and provide stress management training to increase nurses' personal resilience and communication.

4.2. Factors Influencing Nurses' Work Engagement in Integrated Nursing-Care Service Wards. First, job demands of nurses in Integrated Nursing-Care Service wards had a negative effect on work engagement. In Choi's [43] study, a negative relationship between job demands and work engagement was reported, and among the subfactors, emotional labor and work overload had a negative effect on work engagement. The effects of emotional labor and workload on work engagement were reported in many domestic and international studies. As there is a lack of

TABLE 2: Summary of the test results for the hypotheses based on the research framework

research on this topic, it is necessary to explore the relationship between job demands and work engagement in the special environment of nurses in Integrated Nursing-Care Service wards. Second, job resources had a positive effect on nurses' work engagement in Integrated Nursing-Care Service wards. The effect of nurses' work environment on work engagement was reported in previous studies; if nurses are fully aware of and satisfied with their job resources, they are more likely to experience positive work engagement. Therefore, efforts should be made to improve nurses' work environment and increase their awareness of job resources. Third, personal resources had a positive effect on work engagement. The greater the resilience, the higher the work engagement, which is consistent with the findings of Moon et al. [44] and Jang [45]. The effect of resilience on work engagement was confirmed in various studies, and recent studies related to the COVID-19 response showed that resilience plays an important role in the work experience of nurses. Therefore, programs aimed at improving resilience are needed to manage work engagement among nurses in Integrated Nursing-Care Service wards. Based on these findings, in order to effectively manage job burnout among nurses in Integrated Nursing-Care Service wards, efforts should be made to improve job demands, reduce emotional labor and work overload, and enhance job resources by improving nurses' work environment. In addition, programs aimed at enhancing nurses' personal resilience should be actively developed at the hospital organizational level.

4.3. Mediating Effects of Nurses' Burnout in Integrated Nursing-Care Service Wards. The structural model based on superordinate and subordinate factors confirmed the mediating effect of burnout on the relationship between job demands, job resources, and personal resources. Particularly, emotional labor and resilience had a partial mediating

effect of burnout on subordinate factors, whereas satisfaction with the recognition from patients and guardians showed a full mediating effect. First, regarding the relationship between emotional labor and burnout, burnout showed a partial mediating effect, consistent with the findings of Shim [29], as nurses, especially in Integrated Nursing-Care Service wards, have more direct contact with patients, and the burden of emotional labor is greatly felt in the process of hiding their emotions and always treating them in a friendly manner to meet patients' and guardians' expectations of integrated nursing-care services. As a result, nurses are likely to experience burnout due to emotional labor, which affects their job enthusiasm. Therefore, emotional labor needs to be managed in Integrated Nursing-Care Service wards, and intervention programs are needed. Second, satisfaction with the recognition from patients and guardians showed a full mediating effect of burnout in its relationship with job commitment, which is different from the findings of Shim [29], where satisfaction with the recognition from patients and guardians did not directly affect job commitment but indirectly affected burnout. In this study, satisfaction with the recognition from patients and guardians in Integrated Nursing-Care Service wards mediated the relationship between burnout and work engagement, suggesting that good communication and interaction with patients and guardians, along with measures to reduce burnout, play an important role in mitigating work engagement. Third, resilience had an indirect effect on work engagement, and burnout mediated the effect of resilience on work engagement. Although the results of this study differ from those of previous studies, resilience seems to play a role in mitigating burnout and reducing work engagement depending on the characteristics of Integrated Nursing-Care Service wards.

Therefore, programs to enhance nurses' resilience and measures to manage burnout should be implemented. These findings suggest the need for intervention programs and organizational improvements that take into account the work characteristics of nurses in Integrated Nursing-Care Service wards, especially emotional labor, satisfaction with the recognition from patients and caregivers, and resilience. In doing so, we should focus on decreasing nurses' job burnout and increasing their overall job satisfaction.

4.4. Limitations. As this study was limited to nurses in tertiary hospitals, the results should be interpreted with caution, and it is recommended that the study be repeated considering the size of the hospital and various organizational characteristics.

5. Conclusions

This study used the JD-R model to examine the factors affecting burnout and work engagement among nurses in Integrated Nursing-Care Service wards. The structural model analysis substantiated the significant influence of job demands, job resources, and personal resources on both burnout and work engagement, affirming the robust fit of

the proposed model and its applicability to nurses in specific healthcare settings. This study underscores the need for targeted interventions to address burnout management and enhance job enthusiasm among nurses. The key determinants of nurses' work engagement include burnout, nurses' work environment, emotional labor, work overload, and resilience. Notably, heightened emotional labor correlated with increased burnout. This study provides an effective framework for further research, particularly for the development of intervention programs aimed at improving nursing care quality and optimizing workforce management.

5.1. Implications for Nursing Management. This study represents a singular endeavor to substantiate a structural model that delineates the factors influencing the professional commitment of nurses working in Integrated Nursing-Care Service wards. The validated model serves as a pragmatic foundation for the formulation and assessment of nursing interventions in hospitals. Nursing management should prioritize the cultivation of a conducive work milieu, emphasizing the reinforcement of nurses' roles in hospitals. Furthermore, organizational support for initiatives targeting the amelioration of stress and burnout among nurses, coupled with enhancing individual resilience, is recommended for hospitals.

Data Availability

Data supporting the findings of this study are available upon request from the corresponding author. The data are not publicly available due to privacy or ethical restrictions.

Ethical Approval

Data collection began after ethical approval was obtained from the Institutional Ethics Committee (IRB no. 1044396-202201-HR-027-01) of Gachon University.

Conflicts of Interest

The authors declare no conflicts of interest related to funding, writing, editing, approval, or the decision to publish the manuscript.

Authors' Contributions

SHL designed and conducted the study, supervised data collection, administered the project, and performed data analysis, interpretation, and writing of the original manuscript. OYC designed the study, performed data analysis and interpretation, and contributed to the writing of the manuscript. SY contributed to the interpretation of data and writing of the manuscript. OYC curated the data and performed the formal analysis. OYC and SY designed the methodology. SHL and SY supervised the study. SHL, OYC, and SY validated the study and reviewed and edited the manuscript. All authors have read and approved the final manuscript.

Acknowledgments

The research was privately funded without external contributions, and there was no employer involvement.

Aim. This study explored and analyzed the characteristics of bystander types of workplace violence in hospital nurses experiencing horizontal (nurse-to-nurse) violence. The primary research question was “What are the behavioral patterns of bystander types in peer-to-peer violence situations among hospital nurses?”. **Background.** Workplace violence is a result of environmental and structural conflicts, rather than deviant individual perpetrators. Research examining workplace violence suggests that bystanders are not merely witnesses of acts of aggression but can play a substantial role in escalating or deflecting violence. Types of bystander influence power dynamics within a group, resulting in changes in the pattern of violence. **Methods.** Employing a qualitative design, this study conducted focus group interviews with nurses from three tertiary hospitals. The qualitative data collected was analyzed using inductive and qualitative content analysis methods. **Results.** Nine focus group interviews ($n = 26$) were conducted on bystanders’ experiences of workplace violence. A total of 185 analysis units were identified and categorized into three main themes, based on their impact on workplace violence (reinforcing, avoiding, and suppressing) with six subcategories (facilitative reinforcer, diffuse reinforcer, condoning avoider, powerless avoider, empathic suppressor, and interventional suppressor). **Conclusions.** This study delineates a typology of bystander roles in workplace bullying/horizontal violence among nurses, identifying three distinct types of bystanders. The outcomes of workplace violence vary, based on the type of bystander involved as well as the dynamics among bystanders, perpetrators, and victims. **Implications for Nursing Management.** Nursing organizations should educate nurses about the concept of bystanders as this will help nurses understand that even if they may not be perpetrators or victims of workplace violence, they are still implicated as bystanders. Additionally, nursing organizations and leaders should empower nurses to play a positive bystander role.

1. Introduction

Workplace violence between coworkers is defined as “an act of causing another employee physical or mental harm or degrading the working environment by taking advantage of one’s position or relationship in the workplace beyond the scope appropriate for work” [1]. Workplace violence typically targets a particular person, has clear intentions, is recurrent and ongoing, is likely to last for various time periods, and causes long-term job stress [2]. Globally, the prevalence of workplace violence in healthcare is as high as 87.4% [3], with 67.3% and 64.9% of health-care institutions

reporting incidents of workplace violence in North America and Asia, respectively [4]. In Canada, approximately one-third of nurses with less than three years of experience are exposed to workplace violence weekly or daily [5]. The frequency of workplace violence increased during the COVID-19 pandemic [6], making it a prevalent and serious issue in hospital settings.

Workplace bullying among nurses is a critical problem and a significant risk factor that aggravates patient safety in clinical fields. According to previous studies, workplace violence can lead to more frequent medication errors, communication impairment, and lower quality of care

[7–10]. More directly, workplace violence among hospital nurses impairs their physical and psychological health and leads to increased turnover [7–10]. Given the crucial negative consequences of workplace violence, global concerns about workplace violence in clinical settings are gathering attention. Studies have shown that workplace violence can be aggravated not only by the perpetrator's personal disposition and characteristics but also by work environmental factors, such as heavy nursing workload and ineffective systems [11, 12]. Therefore, some aspects of workplace violence should be considered the result of environmental and structural conflicts rather than individual perpetration. Another significant characteristic of workplace violence in nursing context is that most nurses are aware of its existence [13], making it a group issue [10, 14].

In violent situations within a social group, especially between coworkers, the majority often act as witnesses rather than being directly involved as victims or perpetrators. In such social violence scenarios, the negative consequences extend beyond just the victim and perpetrator to also affect the witnesses. In a study examining university students' responses to violent situations on campus, most witnesses felt unsafe and experienced negative consequences from the violence [15]. In nursing contexts, similar phenomena occur when individuals witness violent situations. In Báez-León and colleagues' work [16], most nurses reported feeling uncomfortable and nervous during violent situations, even though they were neither victims nor perpetrators [16]. These negative consequences of violence have been referred to as ripple effects [17] or covictimization [18]. In one previous study, approximately 22% of nurses who witnessed workplace violence considered resigning from their nursing job [17]. Therefore, workplace violence is not solely a dyadic problem involving victim and perpetrator but also a triadic issue that includes witnesses.

Bystanders encompass more than just witnesses or observers; they are individuals who, as members of a social group, can choose their own behavior in response to violence occurring within the social group [18]. In school violence, bystanders are classified as assistants, reinforcers, outsiders, and defenders [19] and further subdivided into bully, puppet-master, victim, avoidant, abdicator, sham, and helpful bystander [20]. Paull et al. [18] classified bystanders of workplace violence into constructive and destructive types and further subdivided them into 13 types depending on whether they were active or passive: instigating, manipulating, collaborating, facilitating, abdicating, avoiding, succumbing, submitting, empathizing, intervening, defusing, sympathizing, and defending.

Bystander in social groups plays a key role because violence patterns can be influenced by the predominant bystander type [18], which in turn affects the power dynamics within the group [18, 21]. For instance, facilitators, such as assistants or reinforcers, encourage and participate in violence by the perpetrator [22], thereby reinforcing the frequency and intensity of the violence [16, 23, 24]. In contrast, victim advocacy types, such as defenders, have a positive effect by supporting the victim and inhibiting the perpetrator's violence [22]. Abdicating types, such as outsiders,

ignore or avoid violent situations, resulting in increased isolation for the victim within the organization [18, 22, 25].

However, there is a lack of studies on bystanders of workplace violence in hospital nursing settings [14]. This gap may persist in part due to the long-standing social tolerance of excessive tension and interpersonal power imbalances within hospital nursing organizations. At times, these aggressive customs are deliberately utilized to immerse novice nurses in the organizational culture [26]. The tolerance for and complicity of nursing organizations in violent situations often render nurse silent witnesses to such incidents in workplace because they accepted it as a norm; nurses may perceive such behavior as the norm within the collective nurse workgroup, thereby normalizing workplace violence as part of their socialization process [27]. In the same vein, some argue that workplace violence among nurses correlates with either the victim's perceived lack of work competence [28] or the characteristics of the nursing organization [29], invoking the oppressed group theory. In this context, nurses may find it easy to witness workplace violence without intervening, as they have not been adequately supported to adopt any role other than that of an abdicator [30]. Moreover, they have never been trained to effectively intervene as appropriate bystanders and address instances of violence [31].

Thus, further research is needed to establish a foundational understanding of how bystander types within nursing organizations differ from those observed in other social groups. In cases of peer-to-peer violence in nursing workplaces, bystanders influence each other's behavior [18, 22]. Additionally, considering that witnessing violence in the workplace is common in clinical settings, more transparent and detailed qualitative data can be gathered more appropriately through group interviews than in one-on-one interviews. Empirical research suggests that focus groups may provide more appropriate settings to elicit sensitive personal information than individual interviews [32]. Thus, in this study, we employed the focus group interview method to facilitate participants with shared experiences to engage in in-depth discussions on the given topic and to share their diverse perspectives through mutual interaction [33]. Therefore, this study aimed to explore and analyze the characteristics of bystander types of workplace violence between hospital nurses in clinical settings. The research question was "What are the behavioral patterns exhibited by bystander types in instances of workplace violence between hospital nurses in clinical settings?"

2. Materials and Methods

2.1. Research Design. We adopted a qualitative study design using focus group interviews and qualitative content analysis to explore the types and characteristics of bystanders of workplace violence between hospital nurses.

2.2. Research Participants. The study population comprised clinical nurses working in general tertiary hospitals. Morgan [33] suggested a total of 18 research participants in three

groups, with a maximum of six people per group, for general focus group interview research. However, during the data collection period in 2021, the national quarantine guidelines for COVID-19 in Korea permitted only small group gatherings of five or fewer people. Consequently, with a research team consisting of two individuals, the plan was to have three research participants per group, totaling six groups. Considering a 20% dropout rate due to the COVID-19 pandemic, the target sample size was 22 nurses.

The inclusion and exclusion criteria were developed considering the *fittingness* of qualitative research. The inclusion criteria for nurses were as follows: (1) provided direct nursing care to inpatients, (2) had more than one year of clinical experience as of the interview date, and (3) worked continuously without leave of absence for more than six months as of the interview date. The exclusion criteria were as follows: (1) had less than one year of clinical experience as of the interview date, (2) were nursing managers who did not provide direct nursing care, and (3) were outpatient and operating room nurses with different nursing delivery systems.

2.3. Data Collection Method and Procedure. We collected data from three university hospitals, each located in one of Korea's major cities: Seoul, Incheon, and Suwon. The selected hospitals had over 1,000 beds, a ratio of beds to nurses ranging from 2.0 to 2.5. Participants were recruited through a research recruitment notice that included the research team's information as well as the purpose, background, and methods of the study. Informed consent was obtained. When dealing with sensitive topics such as workplace violence, group participants should share similar backgrounds and experiences to create a safe and comfortable environment for them to disclose their personal experiences [34]. To construct the focus group, the research team discussed the criteria related to participants' heterogeneity and decided that these should include clinical seniority. To date, knowledge of the clinical nurses' workplace violence experience and bystander behaviors differ from unit characteristics and clinical seniority. [35, 36]. Drawing from existing literature, the research team structured each focus group to comprise members from similar departments but with diverse levels of clinical seniority. To ensure the *fittingness* of the qualitative research, participants were allocated to the focus groups based on the similarity of hospitals and departments, as well as the diversity of their clinical careers. In total, nine groups were formed, each consisting of three participants. No new information emerged after the ninth focus group interview, indicating that saturation was achieved. The data were collected between July and August 2021.

In the focus group interview, one facilitator (the first author, RN, PhD, female) and one assistant (the second author, RN, PhD, male, or the third author, RN, MSN student, female) attended the discussions with the participants. The facilitator was a nursing researcher who had 15.6 years of experience as a hospital nurse with theoretical sensitivity for understanding workplace violence and the

bystander phenomena in the clinical field. The assistants were two nursing researchers with experience in qualitative research. Prior to the interviews, neither the facilitator nor the assistants had any relationship with any of the participants. The participants could get information about the research team through the recruitment notice.

The focus group interviews were conducted outside each hospital in a private, secure setting with a round table, chairs, and refreshments. Each interview was audio-recorded and lasted between 51 and 62 minutes. In total, the nine sessions amounted to 425 minutes.

The focus group research guidelines outlined by Morgan [33] were followed. First, the operational rules and guidelines for the focus group interviews were established. Initially, the facilitator introduced the research team and the reasons for their interest in this topic. Field notes were taken during the interviews by the assistants. Second, the facilitator participated in all discussions, listened to the contents, and asked the research participants additional questions when necessary. Third, to ensure *credibility*, the facilitator and the research assistants reviewed the recordings and took debriefing notes immediately after the focus group interview. If required, the research team reconfirmed the content of the statements. Repeated interviews were carried out for two participants via phone separately. Recordings were immediately transcribed, and the transcripts were validated through member checks. The transcripts were returned to two participants for comments to ensure their reliability and integrity. Fourth, after the focus group interview, the transcripts were analyzed considering words, context, frequency, intensity, and pattern of repeated statements.

2.4. Focus Group Interview Questions. The focus group interview questions were developed through a literature review. As outlined by Paull et al. [18], a bystander is an individual who takes action in violent situations. Furthermore, the behaviors exhibited by other bystanders can serve as triggers or inhibitors for the actions of another bystander [18, 22]. Consequently, the main research questions were structured to inquire about the diverse bystander behaviors observed by the participants, contextual situations surrounding these behaviors, and resulting outcomes and consequences.

The focus group interviews began with introductory questions about the experience as bystanders of workplace violence, after informing participants of the concept of bystanders of workplace violence. The interviews began with low-level structured questions, and then, a funnel strategy was used. The interview questions are presented in Table 1. At the end of the interview, the facilitator summarized the contents of the discussion and confirmed the meaning and intention of the statements.

2.5. Data Analysis. The collected data were analyzed using inductive and qualitative content analysis methods. Qualitative content analysis allowed for a systematic approach to analyzing the qualitative data collected [37]. It operated within the interpretative framework of the hermeneutic paradigm [38], acknowledging multiple subjective realities

TABLE 1: Focus group interview questions.

Category	Questions
Introductory questions	“Have you ever experienced or witnessed violence at work?”
	“When there is violence at work, how do you and your colleagues react?”
	“What was your experience of your coworker’s behavior in a violent situation at work?”
Main questions	“Please tell us your experience of various bystander behavior at workplace violence.”
	“Under what circumstances do you or your colleagues exhibit bystander behavior?”
	“How do you and your peers experience changes in behavior as a result of bystander behavior?”
Closing questions	“Do you have any more comments to share on workplace violence and bystander conduct?”
	“The following is a summary of the interviews conducted so far. Do you agree with us? Or is there anything else that requires clarification or correction?”

and emphasizing the mutual construction of data, which led to the development of individual and multifaceted perceptions of the phenomenon [39, 40]. Through the qualitative content analysis, complex and rich data from research phenomenon were analyzed moving, beyond descriptive categories to uncover underlying meanings inherent in these categories, thereby identifying latent and interpretative content and formulating themes and subthemes [38, 41]. The inductive content analysis method proved suitable for exploring phenomena that may lack comprehensive prior explanations or knowledge [42]. It involved deriving insights directly from the collected raw data [43], thereby enabling researchers to extract direct information without imposing preconceived theoretical perspectives [42]. In every step of data analysis, all authors (including the facilitator and interview assistant) read the transcripts repeatedly, coded the data independently, and reached a consensus through discussions.

2.6. Preparation Phase. The preparatory stage began by selecting units of analysis to categorize the stated content, such as words, phrases, and sentences [39]. With decontextualization and recontextualization, this nonlinear analysis provided an opportunity to organize codes based on similarities and differences in the data, thus facilitating the transition to the next stage where data are separated from the context [41]. This approach allowed for the illumination of all participants’ experiences of the phenomenon [41]. During the condensing and coding phase, decontextualization was carried out [37]. Each researcher repeatedly read the transcribed data and obtained a sense of the whole content. Then, we set the criteria for selecting the analysis unit through discussion. Two experienced authors independently classified the analysis units: Researcher 1 (the first author) extracted 191 analysis units and Researcher 2 (the second author) extracted 161 analysis units. After two rounds of discussion, 185 analysis units were extracted.

2.7. Organization Phase. The organization step comprised open coding (e.g., indexing), categorization, and abstraction of the extracted analysis units [39]. The abstracting process encompassed all types of collected data, including attitudes

and perceptions [37]. Reorganization and recontextualization were carried out during the organization phase [37, 39]. During recontextualization, separated utterances were merged into a new pattern along with their contextual information, which contributed to the abstracting [44]. During the organization phase, a hierarchical structure was established by grounding into categories and subcategories at the various levels of abstraction [38]. To conduct this process, Researchers 1 and 2 independently coded the qualitative data using the extracted 185 analysis units. Open-code data were categorized into several groups using a comparative analysis and a consensus process. The abstraction and naming of each category were discussed several times, and three categories and six subcategories were derived. As an abstraction, a description of the generated categories and naming using content characteristic words was formulated. Based on the categories established during this process, Researcher 1 outlined the types and characteristics of hospital nurses’ bystander behaviors in workplace violence.

All phases of data analysis were iterative and cyclical. The data analysis process was consensus-based in which all three researchers participated. The process and data analysis results were reviewed by a nursing professor, a doctoral hospital nurse with 32 years of clinical and rich qualitative research experience, and two research participants.

2.8. Trustworthiness (Rigor). Based on the criteria outlined by Lincoln and Guba [40], all interviews were recorded and transcribed; vague or inaccurate transcript contents were reconfirmed with the research participants; two study participants validated them by phone. For *fittingness*, the participants were nurses working in a general tertiary hospital with various departments, work characteristics, and careers. A sufficient number of interviews were conducted until the data reached saturation. The final results were reviewed by two participants. The data collection process was recorded and stored to ensure auditability and confirmability. In addition, the research team consisted of experts in qualitative research methodology. Two qualitative research experts (a nursing professor with qualitative research experience and a clinical nurse with 32 years of experience and a doctorate) reviewed the validity of the results.

Subsequently, the results of the final analysis were summarized.

2.9. Ethical Considerations. This study was conducted in accordance with the ethical standards of the Helsinki Declaration after obtaining ethical approval from the Institutional Review Board of Inha University (Inha University Hospital Institutional Review Board No. 2021-03-009).

3. Results and Discussion

3.1. Study Participants. A total of 26 nurses (including two from the research team) participated in the focus group interview, excluding one who had contracted COVID-19. Participants' ($n = 26$) average age was 26.04 ± 1.31 years. The majority were women ($n = 24$, 92.3%). Their average length of clinical experience as nurses was 39.08 ± 11.03 months. All were registered nurses and staff nurses working in general units ($n = 16$), intensive care units, or emergency rooms ($n = 10$) (Table 2).

3.2. Contents Analysis. In the preparation stage of data analysis, the research teams transcribed and read the data repeatedly and understood the overall meaning. Based on this, the research team set the criteria for the codes of analysis according to participants' responses to workplace violence. During the analysis process, the research team agreed that the participants' bystander behavior was influenced by how they perceived workplace violence and the difference in clinical career between the perpetrator, victim, and themselves (bystanders). Additionally, bystander behavior was found to influence workplace violence in departments.

Based on this, 185 analysis units were extracted according to the analysis criteria and classified into three major themes (reinforcing, avoiding, and suppressing) and six subcategories (facilitative reinforcer, diffuse reinforcer, condoning avoider, powerless avoider, empathic suppressor, and interventional suppressor) (Table 3) (Figure 1). Focus group interviews and data analysis were conducted in Korea to ensure data quality. The participant quotes illustrating the findings were translated into English by the second author, a bilingual nursing researcher with extensive clinical experience in the U.S.

3.3. Reinforcer. Participants indicated that bystanders could play a role in reinforcing bullying behavior in clinical settings. Two types of reinforcers were identified: facilitative and diffuse.

This type of behavior was generally observed in nurses with a higher level of experience than the victim and with a higher or equal level of experience than the perpetrator. Therefore, nurses with less experience were more likely to be negatively affected by workplace violence.

3.3.1. Facilitative Reinforcer. The participants suggested that there is a type of bystander who does not instigate but joins

in an act of bullying in the clinical setting. Facilitators adversely affect victims by actively involving themselves in bullying behaviors and are likely to have the same or even higher organizational authority as perpetrators. A facilitator is more likely to collaborate with or defend a bully when they are closely related to the bully.

"It really frustrates me, you know, say I am being bullied by a senior staff member, then some friends of the bully see us and walk over to us, and say things like "do not go easy on her. She has got to learn her lesson."

(Participant 2, Group 1)

"It pisses me off when other people [the bully's friends] chime in or laugh with [the bully] when I am being bullied; it is like I am having multiple bullies at the same time."

(Participant 1, Group 3)

"Sometimes they [bystanders] say, "Why do you make this so hard for my friend?" while laughing with the bully. . . Then, I now fear not just the bully but the whole group that the bully hangs out with."

(Participant 2, Group 6).

3.3.2. Diffuse Reinforcer. Participants suggested that bystanders reinforce bullying by telling other members of an organization about what happened between the perpetrator and the victim. Bystanders of this type reinforce bullying by gossiping in a way that makes the bullying incident look like something that is part of everyday clinical life. Consequently, an organizational climate may be established that perceives workplace aggression as a normative behavior.

"When a bullying incident occurs, there are always people who like spreading the news to others. . . especially during handoffs at a change of shift. . . they talk about it as though it is not that big of a deal."

(Participant 1, Group 7)

"I really do not want to join their gossip. . . but it is practically hard for me to say flat out, "I do not want to engage in gossip" to a group of seniors and rain on their parade . . . so, I would just find an excuse to stay out of it."

(Participant 1, Group 9).

3.4. Avoiders. Participants described bystanders as those who avoided taking action when a bullying event occurred. Two types of avoidant bystanders were identified: condoners and powerless.

This type of bystander behavior was described by nurses with all levels of experience. They mentioned that this type of bystander behavior is observed among nurses who have

TABLE 2: Demographic characteristics of participants ($n = 26$).

Characteristics	Modalities	n (%) or Mean \pm SD
Age (years)		26.04 \pm 1.31
	≤ 25	10 (38.5)
	26~30	16 (61.5)
Gender	Women	24 (92.3)
	Men	2 (7.7)
Marital status	Unmarried	25 (3.8)
	Married	1 (96.2)
Education	Bachelor's	24 (92.3)
	Master's and above	2 (7.7)
Hospital size (beds)	$\geq 2,000$	8 (30.7)
	1,000–2,000	6 (23.1)
	$\leq 1,000$	12 (45.2)
Length of clinical experience (months)		39.08 \pm 11.03
	13–36	10 (38.5)
	37–60	16 (61.5)
Job position	Staff nurse	26 (100.0)

	ICU/ER	10 (38.5)

ICU = intensive care unit; ER = emergency room; SD = standard deviation.

TABLE 3: Types of bystander response behavior against workplace violence.

Categories	Subcategories	Description
Reinforcer	Facilitative reinforcer	Involves themselves in the act of bullying; believes that tense and violent situations are natural and necessary in clinical setting to keep nurses alert A facilitative reinforcer deliberately contributes to the perpetuation or exacerbation of bullying behavior. Their behaviors exacerbate the harmful climate that the bully has cultivated, and thus, enhance workplace violence
	Diffuse reinforcer	Spreads gossip about the bullying incident; believes that tense and violent situations are natural and necessary in clinical setting to keep nurses alert A diffuse reinforcer supports the violent climate by bringing up the witnessed workplace violence incident to other nurses causing them to feel that bullying is normal in the clinical field. Their behaviors exacerbate the harmful climate and, thus, enhance workplace violence
Avoider	Condoning avoider	Takes no action to step into or resolve the situation; believes that tense and violent situations are natural and necessary in clinical setting to keep nurses alert Condoning bystanders may downplay the severity of the situation or deny that workplace violence occurs
	Powerless avoider	Their behaviors exacerbate the harmful climate and enhance workplace violence Takes no action toward bullying despite their belief that violent behavior is wrong and detrimental to the organization. However, powerless bystanders do not intervene in the act or support the victim because of fear of retaliation or lack of experience or empowerment. As a result, their behaviors exacerbate the harmful climate and enhance workplace violence
Suppressor	Empathic suppressor	Checks in with victims and provides emotional support after an incident; believes that violent behavior is wrong and detrimental to the organization. An empathic suppressor may listen to victims and assist them in getting the required help. Thus, they reduce the negative consequences of workplace violence These types of bystanders indirectly provide perpetrators with a signal that workplace violence is unacceptable, which in turn can deter workplace violence
	Interventional suppressor	Uses words or actions to directly intervene in the bullying situation or distract the bully; believes that violent behavior is wrong and detrimental to the organization An interventional suppressor may physically intervene to stop perpetrators, alert authorities, or assist the victim. These types of bystanders directly provide perpetrators with a signal that workplace violence is unacceptable, which in turn can deter workplace violence

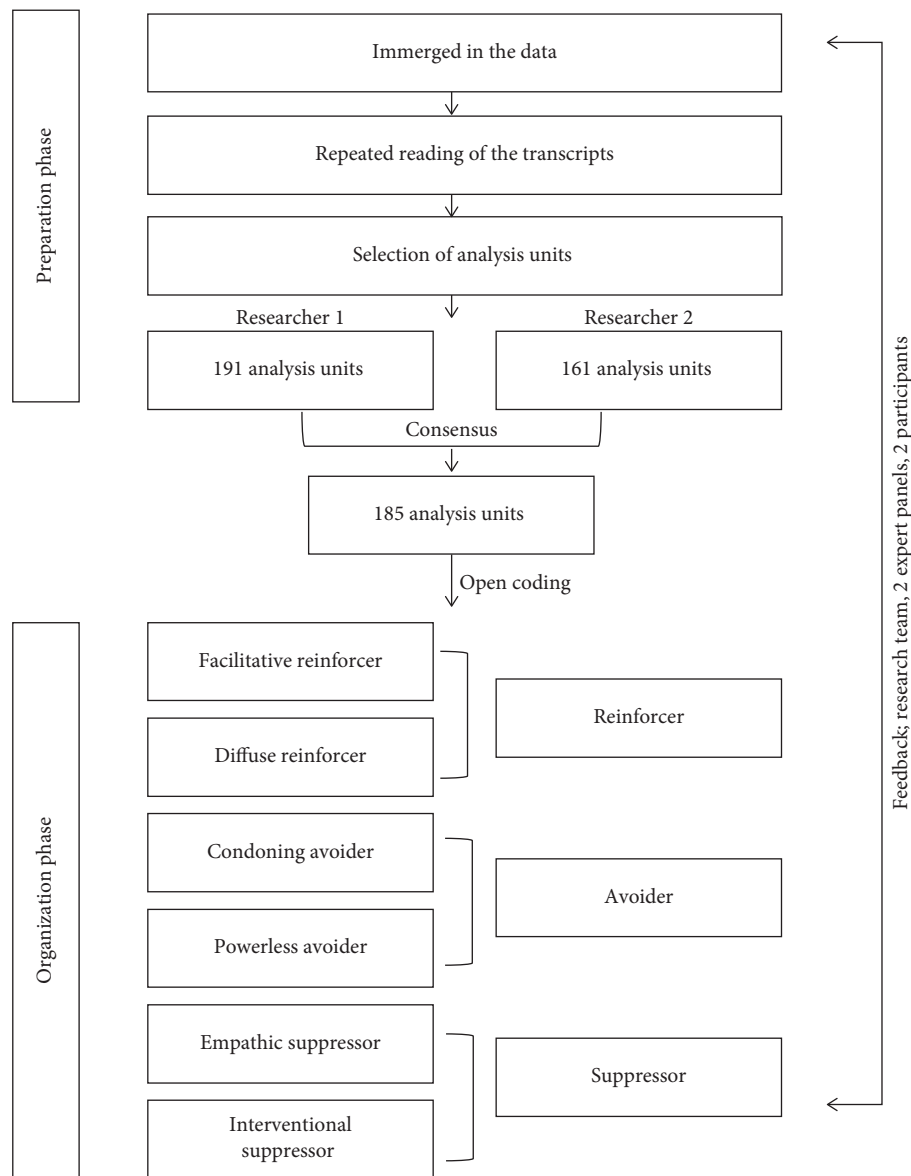

FIGURE 1: Data analysis flowchart.

already accepted workplace violence as part of their daily lives. Acceptance is considered an inevitable form of job training, especially for nurses early in their career. This kind of behavior was also demonstrated when individuals opposed workplace violence but felt powerless to take action because they believed nothing would change.

3.4.1. Condoning Avoider. Condoning avoiders seemed to believe that bullying was an inevitable part of training. They consider bullying to be some kind of a rite of passage or initiation for new nurses. They go so far as to believe acts of bullying are acceptable when they occur between junior and senior staff, assuming that juniors should learn their lessons the hard way.

“Well, I think it [bullying targeted at junior nurses] is inevitable in clinical settings. . . some mistreatment may

be necessary on the job. . . if you are a new nurse and want to be a good one. . . you might need abusive tricks from seniors.”

(Participant 2, Group 3)

“I do not want to see that [bullying behavior by others] . . . I would just leave the scene [without intervening] . . . She [the perpetrator] might have a good reason to be hard on her [victim] . . . and maybe she [victim] deserves it.”

(Participant 3, Group 4).

3.4.2. Powerless Avoider. Participants identified a type of bystander who did not condone bullying but refused to take action because of fear of becoming a target. They would try to leave the scene of the incident or turn a blind eye toward

it. These bystanders, who were often junior nursing staff members, expressed great dissent and distress regarding the workplace violence. As illustrated in the following extracts, the power difference between the bystander and perpetrator is an important factor that renders the bystander powerless to intervene.

“She [the perpetrator] is senior to me; what do you think I can do about it [bullying]? Nothing! Absolutely nothing. I cannot really step in when it is a senior [harassing a junior]. I walked away and returned.”

(Participant 1, Group 2)

“I have never seen anyone stop [in the situation] or come forward, but what can I do when I have little experience?”

(Participant 2, Group 8)

“Sometimes I feel like I am being scolded, and I hate it so much. There is nothing I can do. This is because no one came out.”

(Participant 1, Group 8).

3.5. Suppressor. The suppressor category reflects bystanders who support victims. They intervene in bullying incidents. Nevertheless, they are always wary of bullying in the workplace and do whatever they can. Two subcategories are emerged as follows: empathic and interventional suppressors.

These intervention measures are typically only available to nurses with extensive experience. The recommended intervention methods include engaging in a situation between the perpetrator and the victim, stopping the situation, or redirecting the perpetrator’s focus. However, in the case of nurses with less experience than the perpetrator, this behavior was described as an expression of sympathy and support for the victim rather than a direct action against the perpetrator.

3.5.1. Empathic Suppressor. Participants indicated that bystanders talked to victims privately after the bullying incident and offered them emotional support. These bystanders allowed the victims to know that they were aware of the ongoing bullying incidents in the unit and that they cared about the victims’ feelings. However, they did not take any action to help victims when the bullying occurred. Empathic suppressors were at lower career levels than bullies in the order of seniority based on length of employment.

“When I see one of the new nurses being reprimanded by senior staff, I try to look away. It is hard for me to intervene in such a situation. . . but at the end of a shift I try to find her [the victim] and cheer her up . . . like patting her on the back and saying things like “You are doing great! - I had to go through this too when I was a new nurse.”

(Participant 1, Group 4).

3.5.2. Interventional Suppressor. Participants referred to bystanders who stepped in to stop the bullying act. These bystanders understood the destructive consequences of bullying for the organization. They seem to believe that bullying incidents in a clinical unit increase the stress level of not just the junior staff but also that of the workplace in general. Upon recognizing a bullying incident, they immediately step in and find out what happened by listening to the story from multiple sources, both perpetrators and victims, separately. Most interveners are perceived as being in a position of power in the organizational hierarchy.

“There are instances in which I happen to be the most senior nursing staff member on a shift. If I saw someone bullying another day, I tried to intervene. Previously, I did not care. Now I just tell her “Take it easy!” or call her by her full name like “Ms. so-and-so.” This usually does the trick.” (Participant 2, Group 9)

4. Discussion

This study explored types of bystanders of workplace violence between hospital nurses through qualitative research using focus group interviews. Hospital nurses’ bystander behaviors in nurse-to-nurse workplace violence were classified into three types based on their actions: reinforcer, avoider, and suppressor.

The reinforcing bystanders who intensify workplace violence are categorized into facilitating and diffuse reinforcers. Facilitating reinforcers aggravate the negative consequences of workplace violence by sympathizing with perpetrators’ violent acts and diffuse bystanders make workplace violence commonplace by spreading rumors about it throughout the organization. In this study, nurses in high-power positions within the group displayed reinforcing bystander-type behaviors. Similar to other types of social violence, workplace violence is triggered by a power imbalance among group members [26]. Power imbalance in the clinical field arises from differences in seniority, actual position, and clinical career experience [26, 45]. In these circumstances, it is easy to inflict workplace violence through job training or advising nurses who are new or in a lower career position [46]. In this study, many participants reported that they were exposed to or had observed workplace violence between nurses during job training as novices or advanced beginners. This type of job training has long been recognized as a socialization process unique to nursing organizations, in which workplace violence is recognized as a daily ritual by all perpetrators, victims, and bystanders and has become a social norm [26]. Social norms are the stated or implied rules or standards of conduct that apply to collective behavior [45]. The participants of this study described the reinforcing bystander behaviors as “that kind of thing has always happened.” Workplace violence between perpetrators and victims is “intentional and target-oriented” [26, 46]; reinforcing bystanders do not target

specific people in everyday life. As a nonspecific act, their behavior can be seen as a long-adopted norm of the collective nurse workgroup rather than an act of intentional violence to deliberately suppress the victim. However, the act of strengthening the harm as a reinforcing bystander is accepted as violence by victims and other witnesses, especially by nurses in lower career positions. Hutchinson et al. [47] suggested that organizational tolerance for workplace violence is an important factor influencing bullying behaviors. By allowing the development of a pattern of repeated violent behavior, organizational tolerance and acceptance of workplace violence lead to a new form of intensified aggression. According to Paull et al. [18], aggressive bystander acts increase group tolerance for violence and, hence, reinforce the social norm of accepting workplace violence. This reinforcement worsens the power imbalance within the organization and makes witnesses more fearful of becoming the next victim, exacerbating violence in the group.

The second bystander type identified in this study is the avoider type, who may condone the violence or feel powerless and avoid the situation. Condoning bystander behaviors were observed in members of all levels of clinical careers within the group. "Doing nothing" is the most frequently reported behavior among witnesses of various social violence [14, 48]. This is also observed in nursing organizations, and inaction has been reported as the most common behavior of nurses when witnessing workplace violence [14, 16]. Báez-León et al. [16] highlighted that, when most nurses witness workplace violence, they choose not to engage in it or to remain silent. This was expressed as ignoring, taking no action, or doing nothing [30]. The reasons for being a condoning bystander are different from those for other forms of social violence. Hoxmeier et al. [48] found that the most common reasons for avoiding violent situations among college students were "none of my business" or "unsure of the situation." However, one reason for condoning bystander behavior in the nursing context is the perception of workplace violence as a natural phenomenon in nursing groups. In particular, the participants reported that they did not get involved "because I learned how to do the job that way," and sometimes, they avoided violent situations "to let it happen." In particular, this was reported prominently in workplace violence during the job training of nurses in lower career positions. Participants who experienced or chose the condoning bystander behavior said that those in a lower career position needed to learn the nursing job "with a certain level of tension." Therefore, rather than recognizing workplace violence as a problematic situation, it was recognized as a natural or necessary situation. However, powerless bystanders of workplace violence were different from those who condoned violence. They admitted that workplace violence was prevalent but did not accept that it was natural or justified. Instead, they believed that it could not be prevented or felt helpless to stop it and avoided it. Learned helplessness contributes to neglect of workplace violence in nursing organizations [14, 16]. Another cause of powerless bystander behavior identified in this study was fear of retaliation. Fear of reprisal has been reported in

previous studies as the reason for inaction against workplace violence in nursing organizations [16, 49]. The absence of reprisal fear was a critical influential factor in nurses' intention to help victims of workplace violence [16]. In a previous study, the reasons for reluctance to act against workplace violence were reported as fear of negative influence on oneself (39.7%) and cases in which the perpetrator was too powerful (35.5%) [49]. Fear of reprisal grew stronger when the perpetrator retaliated [24, 50]. Consequently, witnessing violence in the workplace acts as another form of violence for powerless bystanders, and they share the ripple effect of the harm caused by violence [51]. Avoiding bystander behaviors strengthens organizational tolerance for violence in the group by making the victim, as well as witnesses, perceive violence as a natural organizational characteristic [16, 52], resulting in the isolation of victims and the strengthening of violence in organizations [10, 18].

The third type of bystander identified in this study was the suppressor, which was divided into empathic and interventional suppressors. Nurses who understood that workplace violence was an unnecessary immoral practice and an unjust behavior that adversely affected both nurses and patients exhibited this type of behavior. They were classified as groups that expressed sympathy for the victims' situation and groups that chose actions to support them. Empathic suppressors paid attention to workplace violence but were characterized by supporting the victim after the situation was over rather than stopping the incident. As a result, the negative consequences of workplace violence experienced by victims were mitigated; however, the influence of workplace violence prevention was weak. Empathic suppressors were nurses with lower power than perpetrators. They expressed that if the perpetrator had a longer clinical career, they could not stop the perpetrator. In contrast, an interventional suppressor directly engaged in workplace violence and interrupted or stopped the situation to protect the victim and restrain the perpetrator. Interventional suppressors had a higher career status than perpetrators. Suppressor bystanders positively influence workplace violence and its consequences for nursing organizations. Positive bystander behavior had a more significant influence on nursing outcomes than workplace violence did. According to previous studies, when there was a positive perception of bystanders, nursing care quality was better [10] and there were fewer handover errors [53]. Suppressor bystanders not only mitigate the negative consequences of workplace violence by protecting the victim but they also dampen the power imbalance between the perpetrator and the victim by creating group pressure on the perpetrator to stop such incidents [10, 18]. By informing group members that workplace violence is not acceptable, suppressor bystanders can influence organizational norms that tolerate workplace violence [10, 18, 52]. Consequently, the frequency and intensity of workplace violence can be reduced and prevented [18, 22, 25]. Considering that nurses in a higher career position can form supportive subjective norms and reduce fear of reprisal, suppressor bystanders are crucial. Báez-León et al. [16] reported that the right action of a witness can be an important motivator for others.

MacCurtain et al. [49] also emphasized the influence of positive bystanders, stating that positive bystander behaviors of nurses in higher career status with important positions in the department can reflex socially constructed norms. In this regard, organizational strategies to strengthen positive bystanders can be an effective approach to prevent workplace violence [14, 54, 55].

This study has several limitations. First, it employed focus group interviews rather than in-depth individual interviews as the source of qualitative data. This was done because the research team intended to bring out the participants' various experiences regarding workplace violence, including interactions within the interview group. There might have been limitations in deriving the in-depth experience of each individual during this process. Therefore, in future research, the three types of bystander behavioral experiences presented in this study need to be explored more deeply. Second, a limitation of the current study arises due to the research context of the COVID-19 pandemic. The qualitative data were collected in 2021, during the pandemic period. The research team kept in mind that the workplace environmental changes caused by the COVID-19 pandemic could present another bias in the exploration of workplace violence phenomenon. To minimize the potential influence of COVID-19, the research team strived to keep the discussion within the general and comprehensive range of workplace violence and bystander behavior. Additionally, all interviews were conducted on topics unrelated to COVID-19, focusing on the phenomenon itself. Another major change faced by the research team due to the COVID-19 pandemic was the size of the focus group, which included only three participants, owing to the COVID-19-related restrictions. Considering this limitation, we encouraged the participants to interact with each other sufficiently during the interview and were able to reach saturation by involving a sufficient number of groups. Third, the current research participants were recruited from the big tertiary hospitals in the metropolitan cities of South Korea, so the external validity could be limited, and the results should be generalized with caution. To address this limitation and consider the fittingness of the qualitative research, the research team tried to strike a balance between participants' homogeneity and heterogeneity. For the heterogeneity of the participants, clinical seniority was considered an individual difference, and for the homogeneity, the hospital and department were considered to have contextual similarities. Fourth, this study did not utilize a theoretical framework as the basis for constructing its research methodologies. Therefore, further research should employ a useful theoretical framework to explain workplace violence among nurses and its consequences. For example, affective events theory, which posits that workplace events trigger affective reactions that in turn influence employees' attitudes and behaviors [56], could be considered. Fifth, workplace violence experienced by nurses can be categorized as patient-nurse, doctor-nurse, and nurse-nurse. This study explored bystanders' involvement in workplace violence by focusing on violence between nurses. As confirmed in this study, the type of behavior of bystanders in workplace violence is influenced by the individual's perception of the violence (accepted social norms, etc.) and power imbalance between perpetrators, victims, and bystanders. Thus,

nurses' bystander behavior in patient-nurse and doctor-nurse violence may differ from the results of this study. Based on these results, future studies can develop a measurement tool that can measure bystander types in the workplace in a nursing context. A quantitative study is recommended to empirically describe the influence of a positive bystander on the perpetrator, victim, and other bystanders.

5. Conclusions

This study explored specific types of bystanders unique to the nursing context. Three different types of bystanders were identified and categorized by the perceptions of workplace violence as accepted natural norms and power differences in clinical careers between perpetrators, victims, and bystanders. In addition, each type of bystander had a different influence on perpetrators, victims, and other bystanders, thereby aggravating or suppressing workplace violence. This suggests that a strategy can be proposed to overcome the limitations of existing workplace violence prevention policies which focus only on violence between perpetrators and victims and to prevent workplace violence more fundamentally, targeting multiple bystanders. Therefore, nursing organizations must more actively establish strategies that utilize the concept of positive bystanders to prevent violence in the workplace. Specifically, nursing organizations should educate nurses about the concept of bystanders so that the nurses understand that, even if they are not a perpetrator or victim of workplace violence, as bystanders, they are still involved. Additionally, nursing organizations and leaders should empower nurses to play a positive bystander role.

Data Availability

The interview data supporting the findings of this study are available from the corresponding author upon request, for researchers who meet the criteria for accessing confidential data.

Conflicts of Interest

The authors declare that there are no conflicts of interest regarding the publication of this paper.

Acknowledgments

The authors would like to thank all nurses who agreed to participate in this study and actively shared their experiences despite the COVID-19 pandemic. This research was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF) and funded by the Ministry of Science, ICT and Future Planning (NRF-2020 R1F1A1076006).

Aim. To identify the barriers and enablers to the implementation of a national policy to increase and develop the advanced nurse practitioner (ANP) workforce in Ireland. **Background.** The Department of Health (Ireland) introduced a policy to increase the number of ANPs to 2% of the nursing workforce. Evaluation provides information to inform successful policy implementation and development of ANP roles in healthcare services. **Methods.** Qualitative descriptive design. Twenty candidate ANPs participated in four focus groups. Nine key stakeholders were also interviewed. **Results.** Analysis identified four barriers: lack of infrastructural resources; delay in releasing and arranging replacements for candidate ANPs; role resistance from administration, allied healthcare professionals and other nurses; and lack of organisational readiness. The five enablers were: supportive physicians; Nursing and Midwifery Practice Development Units; supportive directors of nursing; role awareness and clarity; and educational preparation. **Conclusions.** This evaluation identifies barriers and enablers to the implementation of a national policy to increase the critical mass of advanced practitioners within the healthcare services. Evaluation at the implementation phase informed the roll-out of future advanced practice initiatives. **Implications for Nursing Management.** To support advanced practice development, leadership, infrastructure, and resource planning are needed to harness known enablers and address identified barriers to the implementation and sustainability of these posts.

1. Introduction

Recent decades have witnessed the growth of Advanced Nurse Practitioner (ANPs) roles. Globally, such roles evidence diversity in the rationale for their development, role focus and functions, role titling and terminology, education and regulation requirements [1], International Council of Nurses (ICN) 2020; [2]. This is noted in the most recent ICN [3] guidelines which aim to provide uniformity in the identification and integration of such roles within systems of healthcare. Evidence of the positive impact of the ANP role include beneficial patient outcomes, continuity and integration of care, clinical leadership and, improved efficiency and cost effectiveness [3–7]. However, to be successful, the introduction of, and succession planning relating to, ANP roles should be linked to identified service needs and involve comprehensive planning along with education and strategic and organisational supports, and evaluation [8, 9]. An increasing empirical focus on the factors that can support the implementation and development of the ANP role is evident. This paper reports on the qualitative findings from an evaluation of the introduction of a policy to increase the number of ANPs in key patient areas [10]. Specifically, the research identified barriers and enablers to the development of the role from the perspective of candidate ANPs (cANP), registered ANPs and key stakeholders.

2. Background and Context

In the Republic of Ireland, the registered ANP role was first accredited in 2002 and is defined as a “career pathway for registered nurses, committed to continuing professional development and clinical supervision, to practice at a higher level of capability as independent, autonomous, and expert practitioners” Nursing and Midwifery Board of Ireland (NMBI). Registered ANPs have competencies that enable them to be senior decision makers, work collaboratively, demonstrate clinical leadership and research skills, undertake advanced physical and/or mental health assessments, and implement evidence-based interventions including prescribing when needed with service users that have complex and multiple needs [11]. Those holding the role are regulated and subject to the Advanced Practice (Nursing) Standards and Requirements published by the NMBI [12] for education and registration of ANPs. To meet the increasing demands within the health service and acknowledging the impact that ANPs were having on patient care, the Department of Health published the document *Developing a Policy for Graduate Specialist and Advanced Nursing & Midwifery Practice: Consultation Paper* [13]. This consultation paper outlined a new structured model for graduate to advanced practice to support the development of a critical mass of nurses and midwives to “address emerging and future service needs and drive integration between services” (p.8). This document identified a goal of increasing the number of ANPs to 2% ($n=700$ approximately) of the nursing and midwifery workforce by 2021 and led to the roll-out of a two-year demonstrator project (the subject of this evaluation). This was followed by the publication of *A Policy*

on the Development of Graduate to Advanced Nursing and Midwifery Practice in 2019 (Department of Health). In Ireland, those nurses preparing to be ANPs are titled “candidate ANPs”; this refers to a nurse who is undertaking an advanced nursing practice Master’s degree education programme which includes both academic and advanced clinical competency requirements. Candidate ANPs are employees within the health services and to undertake the education programme, need protected study leave and to be released from clinical practice.

Evidence suggests that considerations pertinent to the support of ANP roles are both complex and multiple. A scoping review by Whitehead et al. [14] focusing on factors that provide a positive impact identified the importance of a robust candidacy programme, clarity of roles which are identified to address a clear gap in the provision of healthcare, interdisciplinary integration, strong mentorship and ongoing professional development. In Australia, a national system for regulating the credentialing of Nurse Practitioners which sets the standards for assessment and competency requirements is identified as an important factor in supporting advanced practitioner role development [15]. Similarly, Lee et al. [16] comparative analysis of nursing regulatory frameworks between Mexico and the United Kingdom highlights the importance of having regulatory frameworks to ensure a coherent and uniformly understood approach, thereby optimising the development of advanced practice nursing that meets health care needs. Findings of a study of role satisfaction, highlighted that empowerment-related factors were also critical, including collegiality, professional growth and research [17]. Other studies have identified the importance of organisational readiness and policies, governance and future planning in relation to succession and regulation [1, 9, 18, 19]. An understanding of such factors is pivotal to the success of the ANP role and the redress of healthcare needs if sustainable change is to be achieved [14, 20]. Therefore, evaluation of innovations to grow ANP roles and related experiences are imperative to understand factors that enable the development, implementation and sustainability of the role within local contexts. This paper reports on the findings from one part of a multicomponent evaluation study [10] that examined the impact of the national consultation document and the development of a policy to develop ANPs in four key areas: older person’s care, unscheduled care, and respiratory and rheumatology [13]. The aim of the component reported herein was to explore ANPs’ and other stakeholders’ perspectives on the implementation of the policy. The aim was achieved by applying a qualitative descriptive methodology.

3. Methods

3.1. Design, Setting and Participants. A qualitative descriptive approach was used as it enables the exploration of research participants’ perspectives on issues of importance aligned to research questions [21]. The main evaluation study design [10] was informed by the Participatory Evidence-Informed Patient-Centred Process for Advanced Practice Nursing Role Development (PEPPA) and PEPPA-

Plus frameworks which were designed to inform the development, implementation, and evaluation of ANP roles [8, 22]. The PEPPA framework emphasizes strategies to mitigate frequently reported barriers to effective ANP role design and implementation, while PEPPA-Plus provides enhanced guidance for role evaluation. The PEPPA framework has been used in over 25 countries to introduce a variety of advanced nursing and other healthcare provider roles with reported benefits of framework related to role clarity, stakeholder role acceptance and support, and successful role implementation [23]. A freely accessible online toolkit [24] provides detailed guidance on how to implement the stepwise, systematic framework. The frameworks incorporate Donabedian's [25] theory and provide conceptual clarity by distinguishing the structure-process-outcome aspects of the ANP role development that have important considerations within the evaluation process. Importantly, the frameworks provide clarity by distinguishing between short-term, intermediate-term and long-term outcomes of the ANP role which inform the goal and direction of the evaluation.

At policy level, PEPPA provides an evaluation framework that can be used at the three stages of role development namely, (1) introduction, (2) implementation and (3) sustainability. Use of the framework was therefore appropriate to the aim of the overall study, while providing a baseline dataset against which future evaluations can be used to compare progress on factors that influence key outcomes such as waiting list reduction, timely access to services and avoidance of unnecessary hospital admissions.

3.2. Data Collection. In the qualitative component, semi-structured focus group and individual in-depth interviews were conducted to gather data pertinent to experiences of the implementation process, factors impacting upon it and outcomes. Participants were recruited via purposive and snowball sampling methods. Interview guides were developed by the research team from the study aim and objectives, and previous literature on ANPs (see Table 1). The use of interview guides provided for consistency across interviews.

Participants from each of the four key areas (older person's care, unscheduled care, respiratory, and rheumatology) were sought via local gatekeepers. Area managers within Nursing Practice Development where candidate ANPs were recruited, acted as gatekeepers. The sampling strategy used was designed to provide for a national spread, geographical and clinical area diversity and the concept of information power was used to determine data sufficiency [26]. Candidate ANPs were employed in acute healthcare settings, out-patient services, and a number were developing links with community care services. Focus groups were held with each of the four areas in which ANPs were recruited as consequence of policy implementation: older person's care ($n=5$), respiratory ($n=5$), rheumatology ($n=6$) and unscheduled care ($n=4$). The four focus groups were each facilitated by two research team members and were held face-to-face. Individual face-to-face or telephone interviews ($n=9$) were held with other key stakeholders. The key

stakeholders provided perspectives of those with first-hand experience of the ANP policy implementation at individual ANP, local and national levels including clinician candidate ANP supervisors, medical consultants, allied healthcare professionals, and senior nursing managers in local and national settings.

3.3. Data Analysis. Template analysis was employed to explore the data with reference to the study aim. This form of thematic analysis focuses on research conducted within real-world contexts and facilitates the definition and organisation of themes [27, 28]. It is located midway on the inductive-deductive continuum. The approach enables structure and flexibility in how data can be analysed. Template analysis is operationalised via seven steps that were applied as outlined in Table 2 by two of the research team with extensive experience in qualitative research. NVivo 12 Plus [30] software was employed to facilitate the analytical interrogation and management of data.

3.4. Ethical Considerations. Ethical permission to conduct the study was obtained from a university ethics committee and relevant local research ethics committees. Participants were provided with Participant Information Leaflets, with explicit and process approaches to informed consent applied, along with the principles of voluntariness and confidentiality in relation to study participation, data processing and study write-up.

3.5. Findings. Data analysis identified the key barriers and enablers to the implementation of the ANP draft policy as listed in Table 3.

3.6. Barriers to ANP Draft Policy Implementation. The analysis identified four key barriers to the implementation of the policy: lack of infrastructure resources; delay in releasing and arranging staffing replacement for candidate ANPs; role resistance from administration, allied healthcare professionals and other nurses; and lack of organisational readiness.

Candidate ANPs and key stakeholders identified a lack of infrastructure resources such as clinic space, administrative support, office space and a specific ANP administrative identifier code as major barriers to the candidate ANP's ability to develop ANP-led clinics and manage patient caseloads. The lack of clinic space, which is essential for clinical assessments and patient treatments, and administrative support for ANP-led clinics to schedule patient appointments, manage check-in services, patient charts or type referral/letters which were available to medical teams, was perceived as limiting the candidate ANP's ability to effectively fulfil their role.

Organizationally, the resources and the space for people has been a really sticky one for some of the candidates not being able to [have] protected space for assessment and management of patients. (Key Stakeholder 4)

TABLE 1: Semi-structured interview question guide.

Q1	What motivated you to pursue this cANP/ANP role?
Q2	Can you explain how you were recruited?
Q3	Tell us about what is different about your cANP/ANP role in the context of this service?
Q4	Have you experienced any challenges in your new role? What strategies did you use to overcome those challenges?
Q5	What organisational factors enabled you in your role to date?
Q6	What are the arrangements for supervision, support and mentorship with your new role?
Q7	Can you comment on the specific contribution of your role to your specialty area?
Q8	What do you see as the specific contribution since the cANP/ANP role was implemented to: patients/families; the multidisciplinary team; the health service organisation?
Q9	Can you describe the impact of your cANP/ANP role on health service needs?
Q10	If the policy was to be expanded what one thing would you recommend to enhance the process?

TABLE 2: Template analysis [28].

Template analysis step	Application in the current study
1. Data familiarisation and identification Identification of <i>a priori</i> themes	Two of the research team listened to, read and re-read the interview transcripts to facilitate early engagement with and reflection on the interview and focus group data The taxonomy of implementation outcomes [29] and advanced nursing practice literature informed the identification of soft <i>a priori</i> themes (potentially relevant aspects of the data)
2. Preliminary coding	Recurring concepts in the data relating to the research purpose (within and between transcripts) were identified, discussed and operationally defined in NVivo. Codes from the tentative <i>a priori</i> themes were tested against the data
3. Clustering	Developing themes were organised into meaningful clusters. Researchers explored how themes might relate to each other
4. Production of the initial template	As clustering advanced, researchers reached consensus on the initial template
5. Developing the initial template	Openness was maintained to facilitate ongoing refinement of the template
6. Applying the template	Organisation of hierarchical themes advanced in tandem with revisiting the interview transcripts to ensure thorough application of the template
7. Write up	The analytical interpretation was written up, discussed with reference to the study aim and objectives by the overall research team and finalised

TABLE 3: Key Barriers and Enablers to ANP draft policy implementation.

Key barriers	Key enablers
(i) Lack of infrastructure resources; (ii) Delay in releasing and arranging staffing replacement for candidate ANPs; (iii) Role resistance from administration, allied healthcare professionals and other nurses; (iv) Lack of organisational readiness	(i) Supportive physicians; (ii) Nursing and midwifery practice development unit (NMPDU); (iii) Supportive directors of nursing; (iv) Role awareness and role clarity; (v) ANP preparation educational programme

Delays in release and staffing replacement arrangements for candidate ANPs to undertake their education programme and engage in role development were also identified as hindering the process of ANP policy implementation. Because the launch of the policy was rapid, many replacement arrangements were not in place and candidate ANPs frequently found themselves needing to continue working in their previous clinical nurse specialist (CNS) or staff nurse role whilst at the same time, undertake the ANP education programme and start-up new ANP-led patient services. These delays not only created role confusion with physicians, nursing colleagues and patients, but also reduced the time available for candidate ANPs to set-up new clinical

services. At local level, delays with staffing replacement arrangements were linked to the need to fill the vacant CNS posts and overall challenges with succession management.

It took almost a year for us to actually start [the candidacy] in the knowledge and experience appropriate for the ANP role. (ANP Focus Group 1)

At local level, some candidate ANPs reported having experienced role resistance from other grades such as administration, allied healthcare professionals and other nurses. In healthcare organisations with little or no previous experience of ANPs, participants reported that administrative

services were frequently not available to support ANP-led clinics; this was reported to result in a reduction in the number of patients treated by ANPs. Where there was role resistance from nursing colleagues, resistance in recognising the ANP's extended role including authority for patient treatments was also reported. In some cases, allied healthcare professionals were identified as reluctant to accept patient referrals from ANPs, requests for laboratory tests, X-ray ordering or medication prescriptions.

Radiology was a huge area... ordering a chest X-ray... I would have been probably the first one to go through in my hospital. I'm almost two years into the job and literally got it this month, approval to order x-rays. (ANP Focus Group 2)

Due to the accelerated start-up of new candidate ANP roles, organisational readiness was reduced, and many did not have the optimal lead in time to establish governance structures to support role implementation. This also impacted on an organisation's readiness to manage problems that could arise, for example, with clinical supervision or delays in candidate ANP's progression to registration. Whilst formal service-level agreements between the director of nursing, candidate ANP and clinical supervisor were a pre-requisite in the application process for new ANP posts, the overall governance structures were, in places, under-developed at the time of the new policy implementation. Participants reported that having clear governance structures are important to provide clear pathways of communication to help resolve problems. This was also identified as important to provide clarity within the local organisation about the candidate ANP's extended scope of practice such as ordering x-rays and computerised tomography scans, prescribing medication and making patient referrals to other healthcare professionals.

I don't think the hospital was prepared for the policy... we came in on the basis of the policy, but the hospital wasn't prepared for that and hadn't the mechanisms for the structure set up to support it. (ANP Focus Group 4)

3.7. Enablers to ANP Policy Implementation. The analysis identified five key enablers to the implementation of the policy: supportive physicians; the Nursing and Midwifery Practice Development Unit (NMPDU); supportive directors of nursing; role awareness and clarity; and the ANP preparation educational programme.

Physicians, who acted as a clinical supervisor and mentor for candidate ANPs, were identified as one of the factors that were essential to the successful implementation of the policy. Physicians provided support throughout role development and integration by identifying new service needs, negotiating with senior management for resources for candidate ANPs, encouraging other physicians to support ANP initiatives and organising clinical rotations for the education programme. At an individual level, physicians also provided personal encouragement and support. Physicians who participated in

the interview and had trained in other countries with established advanced nursing practice, had a clear understanding of what the ANP role involved, how it could benefit patient services and were active champions of the new cANP roles locally.

The NMPDU and the Unit's project officers were also identified as instrumental to successful policy implementation. These units are part of the Health Services Executive working under the Office of the Nursing and Midwifery Services Director and have a remit to provide strategic development of the nursing and midwifery workforce through workforce planning initiatives and building leadership capacity within nursing and midwifery in Ireland. They supported the candidate ANPs as they transitioned from the role as clinical nurse specialist (CNS)/staff nurse to Registered ANP by guiding them through the application process, clinical portfolio requirements, how to navigate local settings and set agendas for meetings with senior management. At an organisational level, the NMPDU provided a range of supports including templates for job descriptions, memoranda of understanding for clinical supervision so that directors of nursing and candidate ANPs had clarity regarding the role and could use these standard templates to save time from having to design new documents. The NMPDU also supported the development of national standards for competencies required at ANP level which provide role clarity for all stakeholders including physicians supervising candidate ANPs and directors of nursing for signing-off candidate ANPs as being ready for registration.

We have nationally an advanced practice network within the Office of Nursing and Midwifery Service Directorate... When the policy was launched, and the demonstrator site project was launched, we would have supported directors of nursing in their business cases for applications for candidates. (Key Stakeholder 5)

Directors of nursing who facilitated the new ANP roles were also identified as important enablers to the successful implementation of the ANP policy. In hospitals where directors actively supported the new roles, they did so by managing the prompt release of candidates to undertake the programme, facilitating candidate ANPs to navigate barriers, maintaining interest in their progress and providing clear leadership in multi-disciplinary meetings to ensure the effective integration of new ANPs into the healthcare organisation.

Support from their organizations is essential and that's why you need your directors of nursing tuned in very much into what the role is and they [ANPs] need to be part of the senior nursing team. (Key Stakeholder 2)

Role awareness and clarity on how the ANP role differed from other nursing roles was important to the successful integration of new candidate ANPs into the organisation. In organisations with established ANP posts, role awareness at senior nursing management and physician levels was clear

and barriers for new candidate ANPs were reduced. For candidate ANPs working in organisations with little or no experience of the role, they actively worked at raising awareness about their role and managing expectations through various strategies including developing referral pathways to differentiate ANP and CNS roles, presenting at interdisciplinary meetings and conferences and developing job descriptions with consultant involvement.

The education programme, which was set by the national standards and requirements for the ANP [12], was also identified as a key enabler. It was perceived by participants as providing clarity on the academic and clinical requirements of the role, and the competencies for advanced clinical skills and caseload management.

The training was fantastic. I just love what it's opened up.
(ANP Focus Group 4)

4. Discussion

Based on the PEPPA and PEPPA-Plus frameworks [8, 23], this study [10] was carried out at the implementation phase of the new policy to increase the number of ANPs in the health service in Ireland [31]. This paper examined the barriers and enablers to policy implementation identified from the evaluation to better understand the factors influencing the development and integration of new ANP roles into the health services. As in the 2022 report of the Expert Review Body on Nursing and Midwifery [32], the Minister for Health recommended a further increase in the numbers of ANPs, from 2% to a revised target of 3% of the nursing workforce. This highlights the importance and relevance of findings of the evaluation study to support the further development of the ANP role in Ireland. The evaluation findings provide evidence which could inform future roll-out of such policy programmes in Ireland and may also have implications for similar programmes internationally.

A key feature of the ANP policy in Ireland [31], was the role of national organisations, in particular NMPDUs in leading the process of policy implementation. Although ANPs had been employed in Ireland since 2002, for several years the posts were limited. Following the publication of the policy and the increase in posts, this resulted in many of these new ANP roles being introduced into local healthcare organisations not accustomed to starting-up such posts and to clinical areas with few or no existing ANPs to provide mentoring to the candidate ANPs. Thus, the NMPDU guidelines and templates, including ANP job descriptions, provided organisational-level support to directors of nursing who had to set up these new roles rapidly in their organisations and avoid time delays with having to develop job descriptions from scratch. The NMPDU guidelines and templates also provided for consistency across the introduction of the new ANP roles across different clinical areas and multiple healthcare organisations. At candidate ANP-level, the Project Officers within the NMPDU were key in providing mentorship and supporting candidate ANPs as they transitioned from roles as clinical nurse specialists/staff nurses to that of ANP roles involving patient caseload

management, and clinical and professional leadership. Within the international literature on advanced practice, support from mentors or preceptors is recognised as a key factor influencing the successful development and integration of these roles [14].

The role of physicians who provided clinical supervision and mentoring was a key factor enabling policy implementation. However, as the numbers of ANPs increase it is expected that ANPs themselves will become clinical supervisors for future candidate ANPs. Recognising the need for having a coherent approach to clinical supervision, Lee et al. [33] highlight the importance of having national standards for supervision session structures and documentation tools thereby ensuring consistency across different healthcare organisations and universities. Clinical supervision is one factor that may ultimately affect the long-term sustainability of ANP role development and future policy implementation. The barriers to sustainability and progression of advanced nurse practitioners are complex and multi-factorial and include lack of funding and lack of medical, nursing, and organisational support [34]. The issue of clinical supervision and ensuring quality clinical supervision needs to be central in the design and delivery of ANP education programmes to ensure the sustainability of these roles.

With the introduction of new ANPs, major governance and process changes were required so that they could fulfil their extended scope of practice that included prescribing medications, ordering diagnostic tests and X-Rays, and making patient referrals to other healthcare professionals. This impacted on other healthcare professions and structures such as the Local Implementation Groups (LIGs) which were established to provide a multidisciplinary forum where issues could be discussed with the key stakeholders and problems clarified, explored, and resolved with locally mediated solutions. Similarly, Smith et al. [35] in a study of rural nurse practitioners in Australia, identified local health service managers and community supports as important enablers which can define the parameters of advanced nurse practitioner service delivery. In the Irish context, the LIG had the potential to maximise ANP role clarity and understanding within the local healthcare organisation and minimise the likelihood of role resistance.

Candidate ANPs in this evaluation experienced a number of barriers to their role. This may have been due, partly, to the relatively quick implementation of the policy and time needed by the health service to develop organisational readiness. There is growing evidence of the importance of organisational support and change management processes facilitated by leadership to the successful integration of advanced practitioners [14, 36–38]. Similarly, in this study, senior management were identified as having a key role in fostering organisational support and dealing with issues such as lack of recognition or role resistance which can have a negative impact on ability of ANPs to fulfil their role and workload expectations.

The policy initiative to increase the number of ANPs has the potential to greatly enhance healthcare service delivery in Ireland in the long-term. However, for the implementation

of such initiatives to be successful, this will require continued support at national, local and individual levels [35, 37]. In Ireland, this initiative has benefitted from having a clear national policy and regulatory systems, targeted clinical areas, and funding for the new ANP roles in place at the outset. It also benefitted from having the necessary numbers of interested and eligible candidates who were motivated to advance their clinical careers. Although this evaluation study was carried out in the early implementation stage, some candidate ANPs were beginning to express concerns arising from the need for enhanced organisational supports, which, if not in place, could negatively impact on the long-term sustainability of the national policy programme to increase the number of ANPs in the nursing workforce. Whilst the factors influencing job satisfaction are complex, a national survey of advanced nurse practitioners in Taiwan found that organisational commitment was ranked as the most important work-related variable linked to job satisfaction [39]. Similarly, Wood et al. [40] study of the experiences of UK nurse practitioners, links support for advanced practitioners with levels of satisfaction with the role. Creating an organisational culture that is open to the integration of new ANP roles is an ongoing process that will take time. It is recognised that this evaluation was carried out in the early stages of a rapid policy implementation, however, it is also recognised that the long-term sustainability of the policy to develop a critical mass of ANPs to address emerging and future health service needs is at risk unless ANPs are supported adequately by senior management and the healthcare organisation.

5. Conclusion

This evaluation presents findings on the key barriers and enablers to the implementation of a policy to increase the number of ANPs in Ireland. Implementation of national policy initiatives within healthcare organisations is challenging and complex. Policymakers, healthcare funders and organisations need to evaluate such initiatives so that lessons learnt can inform and improve the future development and integration of ANPs within the healthcare system. The knowledge generated contains transformative potential in that it can inform the future design and support of such roles so that they meet evolving healthcare needs and enable ANPs to function independently within their scope of practice.

Data Availability

The qualitative data used to support the findings of this study are included within the article.

Additional Points

Implications for Nursing Management. To support advanced nurse practitioner development, leadership, infrastructure and resource planning are needed to harness known enablers and address identified barriers to the implementation and sustenance of related posts. Lessons learnt from evaluation at

the implementation phase of new policies can inform the future roll-out and long-term sustainability of developments to build advanced nurse practitioner capacity and realise the potential of nurse practitioners in delivery of healthcare.

Ethical Approval

Ethical approval for this study as granted by the Research Ethics Committees of University College Cork and relevant local research ethics committees.

Conflicts of Interest

Authors declare that there are no conflicts of interest.

Acknowledgments

The research was funded by the Nursing and Midwifery Planning Development Unit. Health Services Executive, Ireland.

Aims. To explore the experience of nurses and physicians regarding psychosocial needs of patients with cancer and to describe their perception according to professional category and clinical setting. **Design.** A qualitative descriptive study. **Method.** 14 nurses and 12 physicians were selected from three hospital clinical units and four primary care centers in northern Spain. Data were collected using semistructured interviews. Content analysis was performed using open coding. Reporting of findings followed the COREQ checklist. **Results.** Four themes were identified: the needs of patients with cancer, psychosocial care provided by health professionals, difficulties addressing psychosocial needs, and available resources. According to nurses and physicians, being diagnosed with cancer involves a radical life-changing process, with a profound impact at the psychosocial level. Within the field of psychosocial care, the role perceived by each profession was different. Thus, nurses highlighted the need for these patients to receive emotional support and care, although limited importance is given to psychosocial needs. The role of physicians was more focused on referring these patients to other health professionals. The lack of training or time was one of the main difficulties perceived by the professionals. The family is a fundamental resource and, overall, patients are provided with limited information about other psychosocial resources. At the hospital, the emphasis is placed on physical needs and health professionals experience greater burnout and fear of compassion fatigue. Primary care teams could, therefore, have a primary role in addressing psychosocial needs due to their understanding of each person's context and personal circumstances. **Conclusions.** It is essential for nurses and physicians to consider the psychosocial needs of patients with cancer. However, these needs are not always adequately addressed. Further resources are required to reduce the workload, increase the training of health professionals, and introduce organizational changes to consider psychosocial needs during routine care.

1. Introduction

The importance of integrating psychosocial care within the routine care of patients with cancer has been increasingly recognized [1], especially as numerous unmet psychosocial

needs (PNs) have been identified [2], which can have a negative impact on their quality of life [2, 3].

Previous studies have shown that unmet PNs affect oncology patients with different pathologies such as hematological tumors [4], gynecological cancer [5], or

colorectal cancer [3, 6]. These PN are related to information needs [2, 3, 7], fear of recurrence [3], support needs [5, 7], or psychological issues in general [2]. However, it is also known that patients do not always express their unmet PNs, sometimes for fear of stigmatization or because of difficulties encountered in the physician-patient-relationship [8]. And as expressed by oncology nurses, this can be a problem especially in older cancer patients where the needs may go unnoticed [9].

In psychosocial care, health professionals play a fundamental role. Specifically, nurses play an important role in identifying and meeting unmet psychosocial needs in different contexts, such as clinical units before and after surgery, oncology units, and/or primary care, considered an essential element in the provision of psychosocial care [9]. However, for oncology nurses working in an emotionally charged environment and with time constraints, despite recognizing the importance of PNs, their priority was physical needs, as providing psychosocial care is often a secondary concern, based on the limited time available [10].

Furthermore, this role may be perceived as a challenge, in relation to the particularities of cancer and patient characteristics, because of the lack of support from the team or the institution. Thus, a former study found that providing psychosocial care was an overall satisfying process for nurses, allowing them to grow as individuals, despite coming at a high cost in terms of fatigue and emotional exhaustion [11]. Moreover, there is limited evidence on the role of nurses in addressing PNs in cancer patients in surgical units or in primary care teams [12].

Regarding physicians' response to PNs, according to the perspective of primary care physicians, they identified that their role should be to coordinate patient care, manage comorbidities, and provide information and psychosocial support to patients and their families. However, the role of these primary care professionals is not always close to this ideal, mainly due to communication problems that derive in a lack of updated reports or a lack of clarity regarding their role [13]. These findings are generally consistent with another study on the barriers encountered by primary care physicians caring for cancer patients, which included limited knowledge, lack of time or financial incentives, or less patient trust [14].

Some of the proposals to improve the ability to address these PNs, with considerable consensus among patients and healthcare professionals, would be to change certain behaviors to improve the support provided by the clinical staff and the availability of resources [8]. It would also be advisable to routinely ask patients about their needs and expectations, especially in some patients who may have difficulties in identifying and expressing their demands, e.g., due to advanced age [9].

In terms of training needs, it has been proposed that all primary care providers should be trained to care for the growing number of cancer patients, maintaining good communication and working together with oncologists. These training needs refer to both initial training and continued education throughout their careers, in order to research and implement evidence-based guidelines and assess quality of life in cancer survivors [15].

Therefore, it is still necessary to investigate the involvement of the different health professionals in the approach to PNs, considering the importance of implementing psychosocial assessments in routine care [16]. It is important to incorporate their point of view, since most studies have been carried out from the perspective of patients and/or family members [2, 7] and the perception of health professionals such as cancer surgeons or medical residents is unknown, whose experience has been less explored. In addition, it is becoming increasingly important to address psychosocial demands through multidisciplinary teams [17] considering the main settings (hospital and primary care) where these patients with cancer receive care for years.

The aims of this study were to explore the experience of nurses and physicians regarding psychosocial needs in patients with cancer and to describe their perception according to professional category (nurses/physicians) and clinical setting (hospital/primary care).

2. Methods

2.1. Design. A descriptive qualitative study was conducted. The rationale for this type of research is based on the interest in collecting the subjective and close-up views of health professionals caring for cancer patients in the real clinical setting. The aim is to obtain a straight description of the phenomena, trying to understand their experience in their context in order to carry out an analysis and interpretation of the findings while staying close to the data [18, 19].

2.2. Participants and Settings. This study included nurses and physicians from three clinical units (oncology, general surgery, and otorhinolaryngology surgery) of the Hospital Universitario Central de Asturias (level 3 hospital with about 1000 beds) and from four primary care centers in two urban health districts in Asturias (Northern Spain). The inclusion criteria were being a nurse, physician, or resident physician, being active (i.e., not being on medical leave), and with a minimum of two years of clinical professional experience caring for cancer patients in the hospital or in primary care (not exclusively oncology units). The exclusion criteria were a personal history of cancer, with academic qualifications other than nursing or medicine (psychology and social work), and working in the oncology day hospital (chemotherapy administration center) or the radiotherapy services. Professionals with a heterogeneous profile in terms of sex, age, and professional experience were included in the study applying the following segmentation criteria: profession (nurse/physician) and clinical setting (hospital/primary care).

Purposive sampling was used to select healthcare professionals, either through the research team's contacts or through the involvement of gatekeepers such as the supervisor of the hospital oncology unit. In addition, snowball sampling was used, where participants proposed new health professionals that were relevant to the study. Finally, 26 health professionals (14 nurses and 12 physicians) participated in the study. None of the people contacted refused to participate in the study. Each health professional was

contacted by telephone at their workplace, to explain the study purpose and methodology, together with the voluntary and confidential nature of their participation. The respondents did not receive any compensation for their participation and were informed of the independent nature of this research in relation to their workplace.

2.3. Individual Interviews. Data collection took place via individual semistructured interviews. An interview script was designed, which was previously agreed upon by the work team, mainly addressing the needs of cancer patients, the psychosocial assessment of these patients, and proposals for improving psychosocial care (Table 1).

First, a pilot interview was conducted with the nursing supervisor of the oncology unit of the Hospital Universitario Central de Asturias. The research team who conducted the interviews consisted of a female nursing student who based her final degree project on this study, a social worker (female) with experience in health social work, and a university professor (female) with experience in nursing care research and qualitative methodology. Only the university professor was previously acquainted with some of the participants for work and teaching-related reasons. Both an interviewer and an observer were present during the interviews.

The interviews took place between January and March 2020 in the professionals' workplaces before starting or at the end of their working day, according to the participants' wishes, all of which were audio-recorded. All participants were informed of the study objective and the characteristics of the interviewers (profession and institutions involved in the study). A data collection sheet was used for each professional (sex, age, professional profile, unit, and work center) together with a field diary. The diary was used to compile the characteristics of the meeting (place, duration, consent, voice recording) and a summary of the interview content, as well as other relevant aspects of nonverbal communication, specific cases during their professional experience, etc. The duration of each interview ranged between 10 and 30 minutes. The criterion for terminating the interviews was saturation of the discourse. No interviews had to be repeated.

Each participant was offered the possibility of listening to the recording or reading the interview transcript. Only one nurse requested to review her interview, which was sent to her by e-mail; however, she made no changes to the content.

2.4. Data Analysis. The analysis was carried out in three main phases: preparation of the data, organization of results, and reporting, according to Elo and Kyngäs [20]. In the preparation phase, each complete interview was established as the unit of analysis, establishing that only the manifest content from the verbatim transcription of the interviews would be analyzed, without considering nonverbal language (silences, posture, etc.). Next, an inductive content analysis was conducted, where themes emerged from the data through open coding. Two independent analysts selected two interviews from two participants with a different profile (nurse in a surgical unit and a palliative physician in primary

care) to establish the coding paradigm. To familiarize themselves with the material, each interview was read several times. The intersubjectivity of the team was carried out through the interactive work of the researchers, enriching the analytical capacity and providing a deeper understanding, as opposed to studies where a lone researcher performs the analysis. The contributions of each researcher were valued by the rest of the researchers during the team discussions, with an open mind that subsequently stimulated reflection. The coding system was agreed upon by both researchers, calling on the third researcher in the case of discrepancies. Subsequently, a different analyst completed the coding of all interviews. The codes were grouped into categories that emerged freely in this phase. These categories were then grouped into a higher hierarchical system, organized into themes. When several categories referred to a similar content, they were collapsed. Each category was named using content-characteristic words. Themes were refined in successive rounds of the analysis after gaining a better understanding of the meaning of the nurses' and physicians' experience of PNs. Regarding the last phase, the results were shown in a table, presenting the classification system of the data in codes, subthemes, and topics. The most representative, authentic citations were included in the Results section along with the main themes and subthemes. This helped to increase the trustworthiness of the research, by pointing out to readers what kind of original data lead to the formulated categories. The results were sent to three nurses as a feedback measure with the participants. Throughout the process, the researchers maintained a reflective attitude, being aware of how their thoughts and experiences fed into the analysis, which, in turn, led to changes in themselves as a result of the research process [21]. Nonetheless, they were able to maintain the necessary distance as researchers to see beyond the participants' narratives, as well as contradictions and problems related to their contributions [21].

The rigor of the research is fundamentally based on the clear sample rationale and the triangulation of researchers during the data analysis [22].

For the processing and organization of the data, we used MAXQDA software. The study findings were reported according to the consolidated criteria for reporting qualitative research (COREQ) [23].

2.5. Ethical Considerations. Favorable permission was obtained from the Clinical Research Ethics Committee of Principado of Asturias (REF 314/19) and the Directorate of Nursing of the health district. All participants signed the informed consent form. The study complied with local regulations for the approval of observational studies in Europe and according to the Helsinki Declaration.

3. Results

3.1. Participant Characteristics. The characteristics of the 26 participants are described in Table 2. The distribution by sex was balanced, with 53.8% women. The mean age was

TABLE 1: Semistructured interview guide.

The needs of patients with cancer	<p>(1) In your experience with people with cancer, what kind of needs do you think they have?</p> <p>(2) When caring for cancer patients, what importance is given to psychosocial needs? How do you think this area is currently being assessed? What difficulties do you perceive in making this assessment?</p> <p>(3) Which professionals would be responsible for evaluating these psychosocial needs, at what level of care should this assessment be carried out (referring to specialized hospital care/primary care), have you made referrals to a psychologist/psychiatrist and/or social worker?</p> <p>(4) What training have you received on these topics?</p>
Proposals for improving psychosocial care	<p>(5) What is your opinion of the information given to these patients about resources or support services (psychology, social work)?</p> <p>(6) How do you think the detection of psychosocial needs in people with cancer can be improved?</p>

48.1 years, ranging from 26 to 61 years. In total, 14 nurses and 12 physicians were included. Over half of the professionals (61.5%) worked at the hospital, distributed among three services: two surgical (surgery and otorhinolaryngology) and one medical service (oncology). The remaining professionals worked in primary care, which also included a physician and a nurse from the palliative home care unit. The mean experience was 22.3 years, ranging from 2 to 43 years. Only six professionals (four nurses and two physicians) had training in addressing psychosocial needs. Sixteen professionals had family members or friends with cancer in their close environment.

3.2. The Experience of Nurses and Physicians regarding Psychosocial Needs in Patients with Cancer. No pre-established coding system was established; therefore, the ideas or concepts emerged directly from the data through an inductive analysis. The information was segmented and grouped into four levels of coding (subcodes, codes, subthemes, and themes). Four themes were identified: the needs of patients with cancer, the psychosocial care provided by health professionals, the difficulties in addressing psychosocial needs, and the resources available.

Table 3 describes the needs of patients with cancer according to nurses and physicians. Within this theme, 24 codes and six subthemes were identified. The professionals recounted that these patients need psychological or emotional support throughout the process, although some reject it at first because they feel strong and believe they do not need it. Virtually, all patients have important emotional needs (love, affection, empathy, and feeling supported) because facing cancer reveals their emotional weaknesses. In the process of coming to terms with the diagnosis, taking antidepressants is not always helpful. It is also important to pay attention to how emotions change at different stages after receiving the diagnosis; i.e., emotions change over time, and each patient has a unique emotional response that they may or may not show.

Although they associate having cancer with a loss of functionality and independence, the needs of these patients transcend physical symptoms, and the psychosocial sphere becomes even more of a priority than the physical sphere. They need help to cope with the most frequent symptoms

such as pain or fatigue but also to physically adapt to living with the disease and its chronic sequelae.

They also need to receive information, but it is important to consider each person's wishes about how much they want to receive.

People with cancer want to talk, share, and verbalize their fears, especially regarding facing death or overcoming the social stigma attached to having cancer. These patients demand to be listened to, as they are sometimes unable to vent their feelings to their families and expect healthcare professionals to allow them to express themselves without reservation. They often want to talk about their feelings, about hopelessness in the final stages, about unfulfilled dreams, and about decisions they would like to make, and sharing these thoughts and emotions helps them to cope.

Many professionals likened a cancer diagnosis to a tsunami that forces patients to face uncertainty with difficulty to accept the reality and/or the diagnosis.

“Then they have to adapt their life, reorganize it. There are other people who can't come to terms with this situation, the change that comes first with the diagnosis and then the symptoms, because they need help with basic day-to-day activities, depending on what the disease may cause, and then to adapt their life” (oncologist, hospital).

Finally, these patients require a lot of care that usually starts after the surgical treatment in the hospital and continues at home. Health professionals usually focus on the physical aspects and forget to maintain a holistic view, considering the spiritual needs of the patients, a crucial aspect in a disease of this significance. Some patients feel that health staff show little interest in their religiosity, barely exploring whether they need spiritual help.

Regarding the second theme (Table 4), on the psychosocial care provided by health professionals, two subthemes were identified: the role of each profession (six codes and 18 subcodes) and the reality of their day-to-day work (five codes and 21 subcodes). This theme contains the largest number of codes and subcodes.

Concerning the role of each profession, according to the opinion of nurses and physicians, the assessment of psychosocial needs in these patients can be performed by any

TABLE 2: Characteristics of participants.

Code	Sex	Age	Profession	Clinical setting	Professional experience (years)	Psychosocial training	Family or friends with cancer

				Primary care approach	The healthcare model should take patients' needs more into account The social situation conditions coping and treatment				

professional and the alarm should be raised by anyone who detects unmet psychosocial needs, although nurses are the best suited professionals to identify PNs.

“Nursing. I think the nurse is the one who spends the most time with the patient and we are the ones who see those needs.” (Oncology nurse, hospital).

However, nurses themselves were aware of the importance of conducting a good nursing assessment that addresses this psychosocial sphere.

“Well, the social part isn’t covered for me, no, it’s not covered, neither during the admission nor outside, and. . . there are people or patients who are sad or angry, but you don’t want to dig too much into why. So, if you can, it should be mandatory for me to address that. That area should be covered, just as their pain is covered. Because sometimes the pain can be because you don’t manage it well, because of nerves or because of sadness, or even prolonging the stay because they are alone, because they are afraid. So, for me it’s important, and many stays are lengthened because of social and psychological issues.” (Surgical nurse, hospital).

The role of physicians is primarily to refer patients with PNs to the psychologist and/or social worker. In addition, the characteristics of each professional were significant, depending on their sensitivity, previous experience, or empathy. In addition, it is necessary to have multidisciplinary teams, where the role of the psychologist/psychoncologist is key as the professional who can provide the main emotional support, followed by the social worker, although many professionals are unaware of their field of action.

Regarding the day-to-day reality, not enough importance is given to the psychosocial sphere during health care, although some professionals did believe that it is being adequately assessed (especially in primary care). The approach to the psychosocial sphere could be summarized as “No questions asked, no solution provided” or “It is only addressed once the more clinical part has been resolved.”

“What is life-threatening for this gentleman, the fact that he’s sad or that he has colon cancer? Well, the cancer. You leave the other things aside, the sadness or how he copes with the tumor or his particular disease because first we’re going to solve this and then we’ll see.” (Surgeon, hospital).

In terms of the emotional needs of these patients, some professionals acknowledged that patients refuse psychiatric support because of the stigma toward mental health or the perception that they can cope on their own. However, the emotional sphere is generally neglected, and emotional needs are detected late.

During hospitalization, PNs or psychosocial risk is detected progressively, after several days of hospital stay and especially when hospital discharge is approaching. The professionals at the hospital stated that they are focused on

physical needs and during the first years after diagnosis, the patient with cancer requires hospital care (i.e., surgery, treatments such as chemotherapy and radiotherapy, and checkups). Nonetheless, many professionals agreed that primary care would be the ideal setting for detecting and dealing with PNs, since they are more familiar with the patients’ environment and family and social support network (neighbors, people in the community who can help them, volunteers, etc.). It was also noted that the approach to these PNs occurs in a social context where we live with our backs turned to the disease and death, where we should be more aware of the needs of patients and their social situation, as this often conditions their coping and even their treatment.

Concerning the third theme on the difficulties in dealing with PNs (Table 5), aspects related to the institution or the staff were highlighted. Three subthemes were included, with 10 codes and 6 subcodes. The main difficulties were the lack of training (conceived as voluntary and not favored during working hours) and lack of time. The lack of continuity between hospital and primary care or the scarce relevance of these issues in the clinical history was also noted. The professionals also identified problems of communication and interference with the family, as well as the risk of compassion fatigue, recognizing the fear of becoming too involved and the difficulty of providing emotional support.

“Not having a prescription to say: take this for two minutes, take it like this and come back tomorrow. To accompany, to be with the pain, with the doubt, and well, sometimes just to listen, other times you have to listen and. . . offer a solution.” (Physician, primary care).

The available resources related to psychosocial care were grouped into three subthemes and 11 codes (Table 5): information on resources (the patient is not informed about resources because the professionals themselves are unaware of them), the family as a psychosocial resource (the existing family support determines whether the person needs extra support or not), and the role of associations, which are providing psychological help and resources to cope with the major life change in cancer patients.

3.3. Distinctive Features of the Perception of Psychosocial Needs of Patients in Nursing and Medicine. The need to provide emotional support for cancer patients in nursing was one of the major aspects discussed. Thus, patients need to be able to talk and be listened to in order to face uncertainty and to confront death. The need for care was only mentioned by nurses, highlighting the importance of empathy on behalf of nurses and their need for support in certain situations (patients with ostomies). The physicians affirmed that not everyone needs psychological help, although patients find it difficult to accept the diagnosis.

Regarding the role of each profession, nurses reaffirmed that they perceived that they were the appropriate professional figure to detect PNs, especially during admission, whereas the physicians’ role focused on therapeutic needs (surgical intervention, medical treatment,

TABLE 5: The challenges and resources for the psychosocial approach in patients with cancer.

etc.), explicitly acknowledging their difficulty in addressing emotional needs.

In their day-to-day work, the nurses mostly felt that not enough importance is given to the psychosocial sphere, and therefore, unmet PNs are not attended to, especially at the emotional level, which coincides with the physicians' perception that they do not usually assess the patient's emotional state.

In relation to the difficulties in dealing with PNs, the nurses stated that they lacked the tools to avoid professional burnout, expressing the fear of becoming too involved with patients. They also acknowledged the difficulty of providing emotional support and the lack of professional sensitivity to the psychosocial sphere. Some physicians felt unable to address the patient's psychological experience, recognizing that they lack training going back to the time that they were residents, and acknowledging that they have an excessive workload. Physicians perceived that it would be easier to address this psychosocial sphere in primary care. They were aware of the importance of the psychosocial context and family support because these patients face a long process. Both professionals agreed on the need for training, especially during the workday.

In terms of resources, among the nurses, it was more frequent to refer the patient to social work for information on resources since they themselves were unaware of them. They also affirmed that associations are a support resource for dealing with the radical life change faced by patients, although for many nurses, it is an unknown resource, which they seldom recommend. Some physicians agreed that they could play a more proactive role in offering resources and barely mentioned the role of associations. Nurses acknowledged, to a greater extent, the difficult role of the family when one member has cancer, its value as an essential resource for patients, and the importance of considering a patient/family tandem.

3.4. Distinctive Features of the Perception of Psychosocial Needs of Patients in Hospital vs. Primary Care. The professionals referred that at the hospital, many patients perceive at the onset that they do not need psychological support. Also, there is a sense that not all patients will need it. They are aware that the needs of these patients go beyond the physical sphere; however, according to Western medicine, most of the focus is placed on the physical sphere. Numerous referrals are made from the hospital to other services (especially from medicine to psychology and nursing to social work), and they demand that psychologists/psycho-oncologists should be a part of multidisciplinary teams. Hospital professionals perceived more professional burnout, more fear of compassion fatigue and lack of tools to face this situation. They also recognized the lack of time and excessive workload, which dehumanizes care, although they considered that a regular emotional assessment of patients is important as well as developing the skills to improve communication with patients and families. During hospital visits, professionals are better placed to assess the person's family support, whereas the socioeconomic situation of each family is more well known in primary care.

In contrast, in primary care, professionals emphasized the importance of the medical/nursing tandem, as well as the importance of assessing the circumstances in which patients live, who usually require more support than psychiatric treatment to detect vulnerable situations.

4. Discussion

Our results depict the professionals' perception regarding the PNs of patients with cancer and the role they can assume in responding to that aspect of care. These needs are mainly emotional, because of the impact of the diagnosis and the significance it may have on their future life. It is a tsunami at a personal and family level, where patients want to share their thoughts and emotions because they are afraid of losing their physical independence and are very concerned about uncertainty and death. They also have a need for information about the disease and about resources that they usually receive in associations or through social workers.

Nurses and physicians believe that each professional category has a different role, reflecting on the daily reality where various difficulties arise at the institutional level, together with a lack of time or training. Additionally, the information given to patients about available resources can be improved and the family represents an important resource.

The first category that emerged from the interviews with nurses and physicians was the needs of patients with cancer, who are undergoing a situation of great uncertainty in which they need psychosocial support, especially at the emotional level. According to other authors [2], emotional support is the main psychosocial need found in quantitative studies. Qualitative studies highlight the psychological and spiritual needs of patients related to feelings of fear, hopelessness, uncertainty about the future, sadness, anger, anxiety, frustration, and despair. The main support strategy of the professionals is active listening, empathy, and individual advice on how to cope with their situation. Many patients preferred this type of support to pharmacological treatment, which is what they usually receive [24].

Nurses are more likely to mention the need for patient support, whereas physicians feel that it may not be necessary in all cases [25]. Nurses perceive that patients want to share what they think and feel with them because they cannot always vent to their families and even if nurses or physicians are unable to solve their problems, they find it comforting to be listened to [2].

Professionals and patients coincided in their perception of cancer as a disease with limited chances of survival, which made them both feel vulnerable and in need of new knowledge and skills [14]. The professionals' own emotional vulnerability can make it difficult for them to cope with the requirements of a therapeutic relationship that lasts for years [25]. The importance of spiritual needs should also be recognized, a topic that is complex for nurses to address but critical for patients nearing the end of life. Again, active listening and normalizing conversations about their beliefs and respecting silences are successful communication strategies for providing spiritual care [26].

Concerning the psychosocial care provided by professionals, the respondents highlighted that the main role of nurses was the identification of PNs, whereas physicians oversaw the referral to other professionals, noting the advantage of working in multidisciplinary teams. In our study, physicians and nurses assumed the low importance given to the psychosocial sphere and when comparing their opinion, it was striking how nurses reaffirmed themselves as the main professional to detect PNs [9]. Other studies have also identified how nurses value the need to establish psychosocial care from the moment of diagnosis and accept the importance of their role yet frame it in the context of multidisciplinary teamwork [14]. The privileged role of nurses may be because good communication lays the foundations for a quality clinical relationship with patients and families [10]. In parallel, a systematic and comprehensive nursing assessment favors early detection and management of PNs [27]. It would be interesting to strive for a systematic detection of PNs with standardized and validated tools, such as the distress thermometer in cancer patients [28].

Regarding day-to-day work, in our study, the professionals stated that PNs are generally not assessed, especially during hospital admission where physical needs are prioritized. In particular, the physicians defended primary care as the most favorable environment to consider these needs and to gather information on the patient's environment, whereas primary care physicians and nurses emphasized teamwork between both professionals. The study by Easley et al. [13] found that both hospital and primary care physicians identified family physicians as the ideal professional to coordinate between different specialists, treat comorbidities, and inform and support patients and families. They pointed out the need to improve communication between levels and the training of family physicians. Other studies especially highlighted the role of the primary nurse in the care of patients who have survived cancer and benefit from a comprehensive long-term care model [15]. In general, the professionals appreciated having a figure to coordinate the care to whom both the patient and other care providers could turn to [25]. Also, having this professional as a reference throughout the process could favor the patient's confidence [29]. This longitudinal perspective is an important strength of public health systems with universal coverage and a network of multidisciplinary primary care teams such as that of Spain, in which the family doctor or nurse practitioner can be the professional of reference.

The third category was the difficulties in addressing psychosocial needs, emerging in relation to organization, lack of communication or continuity between levels and workload, or lack of time. In the hospital setting, workload and the lack of tools were of particular concern. In other studies, the lack of training in psychosocial care and communication skills, together with the high burden that prioritizes physical care over psychosocial care, are barriers to the hospital environment [9, 14]. In primary care, professionals identified certain difficulties such as low patient confidence, lack of time, and poor transmission of information from oncology to understand the patient's

follow-up and play a more active role in their care [12]. However, the use of electronic medical records can be a strength to favor communication between levels of care and, therefore, their cooperation [29]. Workload increases due to the scarcity of resources (high patient/professional ratio) and also reduces the time available to provide quality care [29]. Thus, holistic care with the involvement of a multidisciplinary team with good communication between its members would favor the ability to address PNs [14].

While both physicians and nurses generally agreed on the difficulties, physicians placed more emphasis on the lack of training whereas nurses highlighted the fear of emotional exhaustion. In the hospital setting, there is more concern about compassion fatigue where involvement in psychosocial care can lead to emotional exhaustion [27]. Nonetheless, there are authors who emphasize the emotional implication [14] and teamwork [28] as a source of growth, professional satisfaction, and a protective factor against burnout. Additionally, in this environment, working in shifts worsens communication between professionals, and the high workload makes it difficult to deal with PNs because it requires time that may be unavailable.

The last category expressed by the professionals was information on available resources, with nurses relying especially on family and patient associations and physicians assuming that they should be more proactive in their advice on such resources. Regarding the setting, in the hospital, not all cases were considered to need a psychosocial assessment, with referral to a social worker or psychologist/psycho-oncologist when necessary, whereas in primary care, the professionals considered that they were capable of providing support without the need for referral. According to the literature consulted, the role of psycho-oncologists is highly appreciated by nurses and physicians; however, these professionals consider that few cases were referred to them, probably due to the stigma that patients feel toward psychological care and that referrals were made late [29]. Access can be complicated by problems such as waiting lists or noncoverage of this resource by the healthcare provider [25, 29]. Professionals value the family as a support resource from admission to care at discharge, appointments, and treatment plan and have an important role in patient groups and associations [29]. A systematic assessment of patients also helps to identify their family support network, and knowledge of their community assets helps to find resources to turn to for help.

From the point of view of nursing management, understanding the psychosocial needs of cancer patients places an additional demand on nursing staff. By acknowledging this, we underscore the importance of maintaining an appropriate patient-health professional ratio to ensure the delivery of comprehensive psychosocial care. Empowering nurses with the tools and resources to provide optimal psychosocial support can significantly impact the overall well-being of patients. There is evidence that assessing and addressing psychosocial needs in patients with cancer not only is effective but may also be cost saving, because the psychological problems oncological patients are associated with increased healthcare use, healthcare costs, and

economic losses [30]. In addition to the cost effectiveness and cost-utility of psychosocial care, it can be hypothesized that the provision of psychosocial care can reduce both productivity losses and costs of providing informal care [31]. The provision of Psychiatric Mental Health Nurses consultation liaison services contributes to the detection and treatment of individuals with mental healthcare needs in nonmental healthcare settings as oncological services. Psychiatric advanced practice nurses are in the best position to identify the mental health needs of patients and enhance their health-related outcomes [32].

4.1. Limitations and Recommendations. This study has a number of limitations. Although we have had access to professionals (physicians and nurses) from various hospital and primary care services, it would be appropriate to incorporate other services (e.g., oncology day hospital or palliative care unit), considering the characteristics of the hospitals (hospitals >1000 beds vs. hospitals <200 beds) and private centers in order to have a more global view of the phenomenon. It would also be appropriate to continue this line of research by giving a voice to the patients themselves and their relatives in order to confirm our results. Another limitation is that only semistructured interviews were used for data collection. It would be advisable to complement this study by incorporating other qualitative methodologies such as participant observation or focus groups, and even to propose mixed-method studies with quantitative research.

5. Conclusions

According to the perspective of nurses and doctors, psychosocial needs are highly relevant in patients with cancer, as they often require emotional support to cope with a radical change in their lives. However, not enough professional importance is given, and most likely the emotional sphere is neglected because of the priority given to physical or therapeutic needs. The self-perceived role of nurses and physicians differs regarding PNs. Thus, nurses highlighted the need for these patients to receive emotional support and care whereas the role of physicians was more focused on referring these patients to other health professionals. The ideal network would be based on the primary care team as care coordinator and supported by multidisciplinary teams with specialized training, communication skills, time for comprehensive quality care, and information about resources. Through organizational measures and increased resources, the workload can be reduced to systematize the detection of PNs during the health professionals' daily work.

5.1. Implications for Nursing Management. Nurses claimed to be the ideal profession for the detection of psychosocial needs; however, it is necessary to improve nursing assessment and care plans and to give more importance to these needs in patients with cancer. Nursing management positions should be more sensitive to the time and training needs of nurses that can have a major impact on providing better care for people with cancer.

Data Availability

The data that support the findings of this study are available from the corresponding author upon reasonable request.

Conflicts of Interest

The authors declare that there are no conflicts of interest.

Acknowledgments

We would like to acknowledge the effort and kind availability of all the healthcare professionals included in this study. We are also grateful for the collaboration of Liliana Fernández, supervisor of the oncology unit of the Hospital Universitario Central de Asturias, and Noelia Ordieres Buarfa for conducting interviews. Open access funding was enabled and organized by CRUE-G-9 Gold.

The recruitment and retention of in-patient psychiatric mental health registered nurses (PMH-RNs) remains a challenge. This qualitative study sought to identify factors impacting the recruitment and retention of PMH-RNs in acute-care settings. Participants ($N=15$) were recruited for focus groups including one with in-patient unit administrators ($n=4$), two with current PMH-RNs ($n=7$), and two with nursing students ($n=4$). Data were analyzed using a directed content analysis approach. Participants were informed about the study's purpose, procedures, potential risks, and benefits, and they provided verbal consent before participating. Administrators emphasized a focus on retention and described a variety of supports they provided PMH-RNs, including formal and informal support and education. PMH-RNs' most prevalent concerns were their safety, co-worker and/or management challenges, and emotional and/or physical exhaustion. Students also expressed concerns about safety in psychiatric settings and desired more interaction with PMH-RNs. They were also interested in learning more about the specialty as they valued the opportunity to see change in patients. All three groups mentioned a need for more interaction between students and PMH-RNs, while safety concerns were expressed by both PMH-RNs and students. Because PMH-RNs play a critical role for in-patient psychiatric care, recruiting and retaining specialist nurses can focus on increasing student engagement with the PMH-RNs, attending to PMH-RNs' management and staffing concerns, and providing additional resources for responding to events that threaten safety in the workplace to prevent burnout.

1. Introduction

The US has experienced an increased demand for mental health services, in part due to sequelae from the COVID-19 pandemic [1, 2]. A 2022 national survey found that while 42% of US adults reported needing mental health care and 24% reported needing substance use care in the previous 12 months, 43% of respondents also indicated they did not receive needed care [3]. Barriers to accessing mental health care include shortages of mental health providers, geographic maldistribution of providers, a decrease in psychiatric in-patient beds, and a lack of knowledge about how to access care [3–6].

The increased need for mental health care in light of the pandemic has also affected clinician well-being, prompting a call to recognize and address provider stressors [7]. Workplace violence in psychiatric settings, including abusive incidents and threats to safety, affects care delivery and provider health [8, 9]. Psychiatric mental health nursing (PMHN) has responded to the ongoing shortage of mental health providers and these workplace stressors by defining and characterizing the PMHN workforce, describing strategies to meet provider shortages, and encouraging PMHN to champion clinician well-being [5, 10–16].

The PMHN workforce, comprised of both Registered Nurses (RNs) and Advanced Practice Registered Nurses (APRNs), is the second largest group of US mental health professionals [13]. PMHNs play a unique and critical role in providing interdisciplinary, collaborative mental health treatment and care [11, 13]. The majority of PMH-RNs reported practicing in a hospital setting [12]. PMH-RN responsibilities include assessing mental health, applying the nursing process to develop diagnoses and care plans, and administering and monitoring psychobiological treatments [17].

Recruitment and retention of PMHN has been a longstanding concern for the specialty [18–21]. A 2022 survey by Nursing Solutions, Inc. (NSI) of 273 US hospitals reported the turnover rate for PMH-RNs was 20.8%, slightly lower than the 2021 rate of 23.4% and lower than the 2022 average turnover for RNs (22.5%) employed by reporting hospitals [22]. However, the NSI study also reported that behavioral health units experience a 100% cumulative turnover rate of PMH-RNs over five years [22]. Responding hospitals reported that the top ten reasons (in descending order) for RNs leaving their positions were: personal concerns, career advancement, relocation, salary, retirement, unknown reasons, education, scheduling, workload or staffing ratios, and commute. Three of these reasons (retirement, education, and career advancement) are also supported in the literature about psychiatric nursing [11, 12, 23]. A recent PMHN workforce survey found that over half (52.6%) of PMH-RN respondents were in their 50s and 60s, indicating an aging workforce nearing retirement [12]. This 2022 workforce survey found that the number of PMHNs completing a graduate degree since 2010 almost doubled [23], suggesting that at least a portion of PMH-RNs pursue a graduate degree to advance their nursing careers. A reason that may underlie other turnover factors cited in the NSI study is the need for

support and mentoring of RNs new to PMHN practice [19], such as nurse residency programs [21], and continuing education focusing on best PMHN practices [18]. Finally, due to stigma, psychiatric nursing is not seen as a desirable or valuable nursing specialty and may hinder recruitment of students and RNs into PMHN [11, 19, 23].

Recruitment and retention of PMH-RNs are crucial in mental healthcare shortage areas. It is estimated that the shortage of mental health providers across the US affects 163 million people who need care [24]. Nebraska is one state that has a severe shortage of mental health providers, with 90 of 93 counties designated as mental healthcare shortage areas. While an estimated 3.7% of US RNs cited PMH/substance abuse as their primary nursing specialty [25], only 2.9% of Nebraska RNs and APRNs cited PMHN as their primary practice during license renewal [26]. According to a 2020 survey, 10% of urban and 44% of rural responding Nebraska healthcare facilities that employed PMHN contracted for these nurses in the past six months citing lack of applicants, lack of qualified nurses to fill positions, and a need to cover for the absence of regular staff [27]. Two-thirds of the urban healthcare facilities and half of rural facilities who responded to a question about time needed to fill psychiatric nursing positions indicated recruitment spanned four or more months.

Because PMH-RNs' provide essential care, it is important that we better understand PMH-RNs choice of specialty and working environments that promote or deter their recruitments and retention. The Behavioral Health Education Center of Nebraska (BHECN) is a state-funded behavioral health workforce development center with a mission to recruit, train, and retain the behavioral health workforce. To accomplish its mission, BHECN has an interest in understanding PMH-RNs' perspectives related to choosing to practice psychiatric nursing and conditions which help or hinder providing psychiatric nursing care. Therefore, we conducted a study to describe: (1) reasons for PMH-RNs staying or leaving their acute-care psychiatric nursing position and (2) recommendations to improve recruitment, retention, and training of PMH-RNs. Nurse managers are directly responsible for the recruitment and retention of nursing staff and for safe, effective working environments. Results of this study will provide knowledge of PMH-RNs' perceptions of their work environments and their role in clinical care. Understanding these perspectives can help nurse managers provide responsive clinical leadership to help maintain and grow the PMHN workforce.

2. Conceptual Background

Behavioral health workforce development is guided by a Career Pathway or "pipeline" approach for recruitment and retention of providers, including psychiatric mental health nurses [28, 29]. This heuristic provides a systematic approach to career development starting with career education in elementary school and continuing through completion of postsecondary coursework and entry into the workforce [30]. The Pathway approach includes formal or informal mentoring of students by practicing providers. It

also includes students' exposure to actual practice environments through clinical experiences as part of their academic coursework, internships, and observational experiences. Encouraging and mentoring interested students to explore behavioral health careers can stimulate and sustain their interest in these careers [31]. Interacting with the Career Pathways approach are academic-practice partnerships in nursing. These partnerships aim to strengthen collaboration between schools of nursing and health care institutions to improve the quality of both nursing education and clinical nursing care [32]. Academic-practice partnerships can provide the infrastructure for mentoring aspiring psychiatric mental health nurses as well as foster nurses' continuing career development to promote retention. To assure that recruitment and retention efforts for psychiatric mental health nurses address local needs [33], we used qualitative methods to explore PMH-RNs reasons for staying or leaving their acute-care psychiatric nursing positions and their related recommendations for recruitment and retention of PMH-RNs.

3. Materials and Methods

Prior to data collection, the study was screened by the University of Nebraska Medical Center's Institutional Review Board. Because BHECN is a workforce development center and the study was asking about professional practice, the study did not constitute human subjects research as defined at 45CFR46.102 and was exempt from IRB oversight. The study was conducted in accordance with ethical principles including (verbal) informed consent prior to beginning the audio recording. Transcripts were blinded to preserve participant anonymity.

3.1. Participants. Inclusion criteria included being from Nebraska institutions or facilities and being an administrator who supervised PMH-RNs in acute-care settings ($n = 4$), a nurse who practiced as a PMH-RN with current or prior experience in acute-care settings ($n = 7$), or a nursing student who had a psychiatric rotation ($n = 4$).

3.2. Recruitment. We used targeted recruitment through partnerships and personal contacts to advertise the study to organizations and institutions that employ PMH-RN. Additionally, BHECN collaborates with a network of academic programs whose mission is to develop the behavioral health workforce, including the three psychiatric-mental health graduate nursing programs in the state, which advertised the study to students.

3.3. Focus Group Facilitation Guides. Separate facilitation guides were developed following a literature review to identify potential reasons for PMH-RNs leaving their jobs: (1) lack of training to gain necessary skills and knowledge to fulfill PMH-RN responsibilities [18, 34, 35], (2) bullying by other PMH-RNs [36], (3) workplace violence [8, 9], (4) lack of administrative support [37], and (5) lack of resources to improve mental health of PMH-RNs [38].

3.4. Data Collection. Five groups (one administrator, two PMH-RN, and two student groups) were held to accommodate scheduling. Sessions lasted approximately 60 minutes and were facilitated by a PMHN, a social worker, and an epidemiologist between December 14, 2021 and March 18, 2022. The PMHN was prepared to address potential participant distress in discussing workplace violence. Focus groups were conducted via Zoom, audio recorded, and transcribed verbatim. Participants received a \$50 gift card for their participation.

3.5. Data Analysis. Interviews were uploaded into NVivo for analysis using a directed content analysis approach [39, 40]. Two researchers with extensive qualitative analysis experience read through the transcripts several times. The lead analyst (DD) developed codes and a codebook identifying main categories through a deductive approach, which followed the interview guide and inductive development of subcategories along with definitions for each category of participants. A second researcher (PC) reviewed all coding, noting discrepancies, and the two met to resolve conflicts and reach consensus.

The analysts presented the initial coding structure to the research team who provided feedback. Next, the lead analyst reviewed and revised the data based on the feedback, making minor revisions to the codebook. The second analyst then reviewed all coding a final time, noting discrepancies and the two researchers met again to discuss until reaching consensus. Anchor quotations were identified for each main theme. Data credibility relied on data triangulation from the perspectives of administrators, nurses, and students and investigator triangulation by obtaining coding feedback from multiple researchers [41]. An audit trail was used for dependability and confirmability [41].

4. Results

Fifteen people participated in five focus groups: one administrator group ($n = 4$), two PMH-RN groups ($n = 4$, $n = 3$), and two nursing student groups ($n = 2$, $n = 2$). All administrators and students were females. Two PMH-RNs were male and the remaining were females. All PMH-RNs had left acute-care and were working in outpatient settings at the time of the study. They had 71 years of cumulative experience (range 1–37 years) in psychiatric nursing in any setting, but primarily in acute-care units. Table 1 summarizes the themes by participant category with illustrative quotations.

4.1. Administrators

4.1.1. Recruitment Challenges Lead to a Focus on Retention. Recruitment was a significant challenge identified by administrators. The pandemic was mentioned as a contributing factor, citing nurses' ability to obtain higher wages at other health care organizations and the challenges of the pandemic increased older nurses' desire to retire. An administrator said, "We had five agency nurses that were on two back-

TABLE 1: Themes and illustrative quotations.

Group	Theme	Subtheme	Illustrative quotations
Administrators	(1) Recruitment challenges led to a focus on retention	(a) Recruitment was challenging but slightly improving	(i) "We've had three offers out waiting on two, one has accepted so we are now seeing folks coming and wanting to come into behavioral health." (ii) "I'd say about 2 months ago... we started to see a lot of applications had quite a few new hires, 6–8 months prior to that, it was like, okay, is everything in there [application site] right?"
		(b) Focus on retention	(i) "We have another process that if a staff is injured, we follow up with them and several people involved in that and really doing a dive into supporting them through that process, and I think all of that has been helpful for retention." (ii) "Everybody else is doing increasing wages and doing retention bonuses and all those types of things."
	(2) Ongoing processes and support for nurses	(a) Varied and individualized onboarding process (b) Ongoing formal/informal support provided	(i) "...so we make sure that we're talking about more experiences that the orientee needs to have. Are there areas that we need to reinforce, areas that are going well, those type of things so we can keep tailoring it to the needs of the person..." (ii) "So we have a policy on workplace violence, and we put a lot of effort around staff doing incident reports, if they're witnessing it or if it's happening and to come forward, there's an anonymous way to report it." (iii) "We have that stress first aid program, and then we utilize EAP quite a bit..." (iv) "...we brought in individuals who were trained in crisis intervention, how to deal with a violent episode to kind of work through those feelings... I think the ability to have a 911 [emergency] support person to come in and triage, that would be great." (v) "...keep working on getting started in high schools and getting kids interested in mental health."
Nurses	(1) Experience and challenges of their profession	(a) Benefits of the profession	(i) "It's just very rewarding watching people recover from a very, very dark place and just seeing that personal growth and self-discovery." (ii) "...one person can have an impact on one other person, and if you can be that person and have an impact and totally change their life." (iii) "I've worked in some places that have been really unsafe where staff are getting seriously injured or patients are getting injured... and I'm not willing to work in a unit or a facility that has those core safety concerns." (iv) "I've definitely seen a lot of conflict between disciplines and roles when it comes to this career field and my first job there was a lot of conflict because our techs were high school diploma or GED techs, and there was challenges with that. And then my second job, all of our techs had to have at least a bachelor's degree in a related field so that improved a lot of the morale and decreased a lot of the conflict."
		(b) Challenges of the field	(i) "That's where I learned most of my stuff is from veteran nurses who have been through it, and so venting to them after a situation like this really is helpful to me and to get their support and feedback about what happens." (ii) "I would say I'm having more phone conversations with people to let some of that out, whereas, you know it used to be face to face, but now it's more on the phone."
	(2) Sources of current support (formal, informal, and self-care activities)	(i) "We need to find courage from each other. So, if we just had a little more support, I believe the emotional stuff we go through would be beneficial." (ii) "...but also maybe Q&A would be the right word, for people to just talk with other psych nurses, ask the questions they have or definitely like I've already said, I would love to be a preceptor."	
	(3) Need for additional support		

TABLE 1: Continued.

Group	Theme	Subtheme	Illustrative quotations
	(1) Mental health experience	(a) Previous/current work and personal experience	(i) "I feel like we've gotten to see a good variety of psychiatric diseases and mental health disorders and all of that just on like Med Surg floors and everything." (ii) "I specifically work at [a rehabilitation facility] and so by working there I feel like I get to work a lot not just in behavioral health but also like helping patients with their physical health. . ."
		(b) Clinical experience	(i) "So we got to observe quite a few mental status exams, a lot of therapeutic communication and trying to de-escalate situation as well as . . . their daily routine. . . the nurses were kind of spread thin so were in the way a lot trying to help them. . ."
Students	(2) Concerns about the PMH specialty		(i) "I've been hearing it . . . just [students] thinking it's all violent patients but it's not. I think that's a big thing that worries some people." (ii) "I also said that my biggest concern is safety."
	(3) Desire to know more about and interest in psychiatric nursing		(i) "They (nurses) sit in with the doctor, with the patients, and kind of talk about what's going on. We haven't had the opportunity to attend those meetings yet and I kind of would like to. I think it would be interesting to hear about and observe how those meetings [go] . . ." (ii) "I really wish we would be able to follow those nurses on the psych unit . . . on a nursing standpoint, we're not getting anything really, truly productive out of it."

to-back contracts, and they all left at the same time when COVID[-19] kind of changed their income and so they took contracts elsewhere.” Other known reasons for nurses leaving were a desire to work with a different population or to have more flexible hours. Despite challenges, administrators felt positive that recruitment was improving as they started to get more candidates and were filling open positions. An administrator described how six to eight months prior they only had a few candidates for open positions but now “we’ve had three offers out waiting on two, one has accepted so we are now seeing folks coming and wanting to come into behavioral health.”

Employee retention was a major focus, viewed as a long-term process that starts with recruitment and “pipeline” development. One strategy was precepting students as part of concentrated clinical learning experiences. A participant noted, “We’ll be precepting two students that have an interest in Psych. . .and so we would be interested in offering them positions if things work out and so (we are) kind of excited to have that opportunity.” Another noted the importance of starting early and a need “to keep working on getting started in high schools and getting kids interested in mental health.”

Administrators also indicated their organizations were increasing wages and/or providing support to reduce stress to improve retention. As one participant mentioned, “We have another process that if a staff is injured, we follow up with them and several people involved in that and really doing a dive into supporting them through that process, and I think all of that has been helpful for retention.” While much of the discussion revolved around trying to recruit and retain nurses in the short term, one administrator did note the importance of other programming to ensure they stay long term.

4.1.2. Ongoing Processes and Support for Nurses. Administrators had a variety of processes to onboard new nurses to their facility, including a mixture of online and in-person training with mentorship from more experienced nurses. Administrators appeared to primarily focus on individualized onboarding, which was often based on the nurses’ previous experience as well as the type of position (e.g., contract vs. full-time).

Administrators mentioned a wide offering of support for their staff, including formal processes (e.g., Employee Assistance Programs (EAP), wellness committee events), informal processes (e.g., mentor), and education or training (e.g., ways to prevent lateral violence or hostility between co-workers). While none of the administrators discussed any instances of workplace bullying or violence, two mentioned they had direct training about it. For example, one administrator said, “So we have a policy on workplace violence, and we put a lot of effort around staff doing incident reports, if they’re witnessing it or if it’s happening and to come forward, there’s an anonymous way to report it.”

Specifically when discussing how they supported staff following a violent event or altercation involving a patient, administrators mentioned they primarily focused on

convening huddles immediately following the event to debrief. If administrators noticed a staff person needing additional support following the event, they would individually reach out. As one participant noted, “The debriefing and then if it’s very apparent that somebody really needs some support, then we individually reach out to them and just offer that assurance and refer them to EAP if need be.”

4.1.3. Needed Support for Nurses and the Profession.

When discussing ways to better support PMH-RNs and the nursing profession in general, administrators identified several ideas including a need for care options, in-depth or triage support, and engaging high school students. Regarding a need for more care options, two administrators mentioned the lack of facilities for extremely violent patients as a challenge. An administrator explained, “you’re often looking at months (to get them into a more secure facility); we are not equipped to handle people that are extremely violent to other staff. . .as well as to other patients.” Another administrator described a need for better triage support following staff injury. This administrator stated “. . .we brought in individuals who were trained in crisis intervention, how to deal with a violent episode to kind of work through those feeling. . .I think the ability to have a 911 (emergency) support person to come in and triage, that would be great.”

4.2. Nurses

4.2.1. Experience and Challenges of Their Profession. All PMH-RNs described how they valued their profession and found it rewarding. One nurse said, “It’s just very rewarding watching people recover from a very, very dark place and just seeing that personal growth and self-discovery.” However, all the nurses had left acute care and approximately half had considered leaving PMHN altogether. Despite a variety of challenges expressed, the most often expressed concern was about their own safety and previous encounters with violence. As one participant explained, “I’ve worked in some places that have been really unsafe where staff are getting seriously injured or patients are getting injured. . .and I’m not willing to work in a unit or a facility that has those core safety concerns.” Other top concerns were challenges with co-workers or management and feeling unappreciated. One nurse described a previous facility and why she left, “. . .the lateral incivility at work, leadership didn’t listen at all, and there was no training there.”

Nurses expressed they were emotionally and/or physically exhausted and that the COVID-19 pandemic led to burnout. As one nurse noted, “. . .burnout (has been) a huge aspect (with) psych nurses just because our patient care is so difficult. . .but COVID[-19] especially made it worse.” Mask policies during the COVID-19 pandemic also presented a challenge. “When you have someone who’s in psychosis or manic and very paranoid, having to wear a mask around them hinders your ability to form any kind of therapeutic relationship.” Other concerns or challenges mentioned by nurses included dealing with staffing shortages, a lack of

community support or understanding for mental health, and maintaining work/life balance. For example, one nurse stated, "I think that a lot of times people, when you tell them you work in Psych, they have an idea of what that means and it is not what it really means. . . I don't think people understand mental illness at all." The need to provide staffing seven days a week for in-patient settings was also a challenge. One nurse mentioned, "It's hard for my family, I have a baby at home and it's hard to work every other weekend and to be obligated to work holidays as he's growing up, I'm not sure I'm willing to do that."

4.2.2. Sources of Current Support. Like the administrators, nurses described various formal (e.g., EAP and wellness committee events) supports, although not all participants were familiar with these resources. The primary source of informal support focused on conversing with peers and veteran staff. For example, one nurse said, "That's where I learned most of my stuff is from veteran nurses who have been through it, and so venting to them after a situation like this (a violent event or situation) really is helpful to me and to get their support and feedback about what happens." Nurses also discussed various self-care strategies that supported their mental and physical well-being, including conversing or spending time with friends, exercising, spending time alone or with family, although some of these practices were impacted by the pandemic. One nurse said, "Exercise for me, but you couldn't go to the gym with COVID[-19]." Consistent with the administrators, nurses mentioned the primary support following a violent event was through debriefing huddles. One nurse stated, "Everybody involved in the situation will always get together and we kind of talk about what happened, what went well, what didn't go well."

4.2.3. Need for Additional Support. Although the PMH-RNs mentioned huddles as a supportive process, not all the participants felt they were useful as implemented. A participant explained how the huddles actually led to increased stress by taking involved staff away from their other duties, particularly when working on an under-staffed unit.

"It was just kind of, OK, we have to do this. . . We're going to have, you know, 30 seconds and we're just going to move on, without really the full weight of what can we learn from this situation. . . In spite of conversations that were had, (administrators) were very good about superficial level saying, yeah, we were listening, we care, but we're not going to do anything different than this process. . ."

"Or we have this safety huddle, which most of the people that seem to go to that seemed to have all the time in the world to spend all this time discussing all this stuff. I was like, I have to get back down there, there's only one person down there. The environment, it just didn't seem like the rest of the world understood what was actually happening on the unit and how really unsafe at times. . ."

PMH-RNs described multiple needs for additional support for themselves and the profession. One frequently mentioned need was for additional staff at in-patient facilities; however, this was usually in reference to prior positions. Another requested item was more support following a violent event, exemplified by "there needs to be. . . more support for that because it can be physically as well as mentally damaging to be assaulted." Relatedly and like administrators, PMH-RNs mentioned a need for more care options, including residential options and housing. Other support for current PMH-RNs included more education and more support from co-workers. One nurse stated, "We need to find courage from each other. So, if we just had a little more support, I believe the emotional stuff we go through would be beneficial."

To support interest in their profession, another top need identified was for increased interaction with students. PMH-RNs had different ideas on how to best do this, such as having a mandatory psychiatric nursing clinical rotation or having opportunities to present to students to explain the psychiatric nursing role. One nurse described that in her first job, she would ". . . talk about what I did and what my career was, I think that if real psych nurses did that in schools, it could be beneficial."

4.3. Students

4.3.1. Mental Health Experience. Students' clinical rotation experience varied in length (8–14 weeks) and the number of sites (1–3). When discussing their experiences with mental health patients, students most often described their experience through either their own work, personal experience, or other clinical rotations. A student said she had been "a CNA (certified nursing assistant) for the last 10 years. . . we do see a lot of psych cases. . . so that is kind of helpful to have that experience." Regarding experiences in other rotations, a student noted, "I feel like we've gotten to see a good variety of psychiatric diseases and mental health disorders and all of that just on like Med Surg floors and everything." However, students felt like they had gained little experience with PMH-RNs and had a limited understanding of what PMH-RNs actually do. One student stated, "A lot of what they do is passing meds and making sure everyone is compliant with their medication." While another student said, "I think a lot of students don't really understand it."

4.3.2. Concerns about the PMH Specialty. Students' primary concern was safety and experiencing violent patients. A student mentioned concerns she heard from other students, "I've been hearing it. . . just (students) thinking it's all violent patients but it's not. I think that's a big thing that worries some people." Another stated "I think for me, at least, a big concern with that is safety. A lot of what I've seen is nurses not handling the situation as well as they could of." The other major concern about PMHN was the stigma associated with mental health. One student described that despite advancements in education and increased awareness of mental health issues, there is still a significant stigma that exists;

however, she believed the nursing students needed to become more comfortable working with mental health patients as “. . . you are going to have these patients no matter what.”

4.3.3. Desire to Know More about and Interest in Psychiatric Nursing. Despite their concerns, students wanted to learn more about and were interested in psychiatric nursing. When asked about their experience on getting more involvement working around PMH-RNs, they desired to have more direct interaction with nurses and to see PMH-RNs in a greater variety of settings. One student said, “They (nurses) sit in with the doctor, with the patients, and kind of talk about what’s going on. We have not had the opportunity to attend those meetings yet and I kind of would like to. I think it would be interesting to hear about and observe how those meetings (go). . .” Additionally, following the completion of the questions in the focus group guide, the students had multiple questions about the experiences of the facilitator, an experienced PMH-RN who had worked in a variety of settings. Students asked her to explain more of what she did as a psychiatric nurse, what a typical case load was like, and what the typical hours were. Students’ motivation to join the field appeared to stem from a desire to see positive change in patients. They believed psychiatric nursing would allow them to care for patients in ways that promote recovery/remission and an overall better quality of life.

5. Discussion

The purpose of this study was to understand the perspectives of administrators, PMH-RNs, and students on factors affecting recruitment and retention of acute-care PMH-RNs. Three commonalities across these groups emerged. First, each group desired more interaction between nursing students and PMH-RNs. Administrators identified preceptorships as a method to recruit students into the PMHN specialty. PMH-RNs perceived that students were not familiar enough with the specialty. Students indicated that clinical experiences do not give them enough interactions with PMH-RNs and asked many questions about the roles of PMH-RNs. As commented by nurses and administrators, experienced PMH-RNs are a great asset for the organization, newly hired nurses, and patients. Based on PMH-RNs suggestions, nursing classroom experiences could include presentations by clinical PMH-RNs to demystify the roles and functions of PMH-RNs and encourage students to choose psychiatric nursing as their clinical specialty.

Nurses believed psychiatric nursing rotations should be mandatory for nursing students, but students thought all nursing students receive some kind of experience and knowledge about psychiatric care, even if not directly through a psychiatric rotation. Undergraduate nursing programs have latitude in meeting accreditation standards of professional nursing organizations and state boards of nursing but are limited by the amount of information needed to be presented within the program’s credit hours. Although basic psychiatric nursing knowledge and skills are taught based on national standards [42], programs vary in

the type and length of psychiatric clinical experiences, resulting in limited opportunities for learning the in-patient psychiatric nursing role in some programs. Thus, more concerted curricula efforts are needed to attract nurses to practice psychiatric nursing. Developing academic-practice partnerships, practice models that integrate best psychiatric nursing practices with clinical simulation, and basic competencies for psychiatric nursing faculty and preceptors have been identified as priorities to improve PMHN education [35]. Mentoring students by PMH-RNs through classroom presentations or through preceptorships are examples of the types of academic-practice partnerships that will give students an opportunity for additional PMHN experiences without straining current content or increasing clinical credit hours.

Second, all groups addressed safety concerns experienced by PMH-RNs with extensive discussion about violent incidents and how such incidents can physically and psychologically affect nurses. Based on our results, violent encounters with patients were not an infrequent occurrence in psychiatric acute-care settings. While there are some safety protocols and follow-up measures being implemented, nurses expressed their desire to see more investment of resources to prevent violent encounters and support nurses after incidents occur.

At the organizational level, the prevalence of workplace violence is significantly higher in psychiatric settings than in other healthcare settings [9]. A national survey of PMHNs found that less than two-thirds of participants reported feeling safe or very safe in their workplace [23]. Similar to our findings, survey participants cited patient acuity, need for administrative support, lack of staff training, and low staff-to-patient ratios as factors contributing to unsafe work settings. In addition, nurses in our focus groups cited support from colleagues, conducting debriefing “huddles” with consideration for nurses’ other duties, and providing quality nursing care after a violent patient-care event as protective factors for retention. Experienced nurses serving as mentors were cited as valued, supportive colleagues, so retirement of nurses may limit the availability of experienced nurses who can serve in this role.

Administrators and nurses in our study indicated their environment is not equipped or suitable for the level of care some patients need. Administrators noted long wait-times to transfer patients with more severe illness to other psychiatric facilities, which reflect the national shortage of psychiatric beds [4]. PMH-RNs also indicated a need for more residential facilities and better housing in the community for patients, suggesting that nurses understood that social determinants of health contributed to patients’ relapse and need for hospitalization. Relatedly, a shortage of healthcare providers in psychiatric nursing settings contributed to the inability or difficulty handling violent incidents as suggested in the literature [43]. Nevertheless, it is important to better support psychiatric nursing staff as evidence indicates that workplace assault or violence is positively associated with occupational stress and negatively associated with well-being [9].

Third, nurses and students commented on the stigma of caring for patients with mental illness. While there has been an increased awareness of mental illness in the general population [44], stigma is still associated with mental illness in the US. Negative views about mental illness can translate to negative perceptions of the psychiatric nursing workforce. Stigma within nursing education programs and the belief that medical-surgical experience is needed prior to specializing in PMHN further contribute to recruitment barriers [19, 23]. Phoenix suggested that because psychiatric nursing work is largely relationship-based and lacks the profession's visual signifiers (e.g., stethoscopes and scrubs); it can be a disadvantage for recruiting nurses into the specialty [13]. Students said that they cared for patients with mental health needs in medical-surgical settings, so developing experiences for PMH students in primary care that address patients' physical and mental health needs can enhance PMH-RNs' ability to provide integrated care [45] and may increase students' interest in PMHN.

Previous studies found that at the individual level, negative attitudes of psychiatric nursing as a career [46], stress, burnout [47], and lower job satisfaction [48] may explain the high turnover intention in PMH-RNs. Participants in our focus groups also identified these factors. At the organizational level, lack of in-service education and advanced training [34], negative working relationships [33], and procedural fairness concerning performance appraisal [49] were found to be associated with higher turnover intention. In our study, comments from PMH-RNs suggested that lack of training and interpersonal problems among staff were reasons for leaving the in-patient setting. Although PMH-RNs appreciated administrative support from nurse managers, they also indicated additional types of support were needed. Exploration of leadership roles of unit-level nurse managers may help identify those that enhance staff satisfaction as well as patient care. For example, Perkins, Bamgbade, and Bourdeanu found that higher job satisfaction was related to managers who were able to mentor staff, monitor the unit milieu, and direct unit activities by clarifying expectations and problem-solving [50]. While staffing issues, such as 24-hour coverage and weekend work, are similar across in-patient settings, they may add to PMH-RNs' decisions to take noninpatient positions in PMHN or other specialties, especially if other aspects of the clinical setting are negative.

Addressing nursing turnover is critical as it can decrease the quality of care and increase hiring costs for hospitals [51]. The average cost of turnover for a bedside nurse is \$52,350 and a 1% decrease in nurse turnover saves a hospital \$380,600 per year [22]. With mental health issues on the rise and increasing turnover and dissatisfaction among the current nursing workforce, it is critical to improve the physical and mental well-being of PMH-RNs and increase retention rates. Additionally, it is imperative government agencies and healthcare systems understand the significant contribution of psychiatric nursing in mental health treatment [13] and ways to recruit nurses into this specialty.

Study limitations include the small sample size. Despite extensive outreach efforts to recruit, only PMH-RNs who

had left the acute-care setting agreed to participate, so we did not have the perspective of PMH-RNs who currently work in an acute-care facility which may bias results. Inpatient staffing shortages and high levels of COVID-19-related provider stress may have deterred in-patient PMH-RNs from participating. However, some participants had more than 10 years of experience in the in-patient PMH setting. All participants were recruited from urban healthcare facilities or colleges, which limits generalizability. Additionally, the virtual Zoom sessions may have affected information sharing. Nonetheless, identified themes were congruent with other studies and provide insight into the psychiatric nursing experiences of administrators, PMH-RNs, and students. These experiences provide a basis for recommendations to enhance recruitment and retention of PMH-RNs.

6. Conclusions

This qualitative study described perspectives about recruitment and retention of PMH-RNs. Interview data from administrators, PMH-RNs, and students indicated that increased interactions between students and PMH-RNs would increase students' interest in psychiatric nursing as well as satisfy PMH-RNs' desire to promote their specialization. Workplace violence and stress, exacerbated by understaffing, lack of understanding of the PMH-RN role, and stigma about mental health were cited as negatively affecting both recruitment and retention of PMH-RN in acute-care settings. Recommendations for improving recruitment and retention include strengthening academic-practice partnerships, increasing resources to prevent and address the aftermath of patient-initiated violence, and promoting the public visibility and importance of psychiatric mental health nursing.

Moving forward, it is crucial to consider the insights provided by this study to formulate effective strategies for improving recruitment, retention, and training of PMH-RNs. By implementing targeted interventions, such as nurse residency programs, continuing education initiatives, and efforts to combat stigma surrounding psychiatric nursing, the aim is to create supportive and conducive working environments that encourage the growth and sustainability of the PMHN workforce. These measures are vital for creating supportive environments that foster the growth and sustainability of the PMHN workforce, ultimately ensuring high-quality mental health care for those in need.

Data Availability

The focus group transcript data used to support the findings of this study are available from the corresponding author upon reasonable request.

Disclosure

The research was conducted as part of BHECN's statewide behavioral health workforce development efforts and not

directly related to the practice locations or participants in the study.

Conflicts of Interest

The authors declare that there are no conflicts of interest regarding the publication of this paper.

Authors' Contributions

Co-authors affiliated with BHECN planned, conducted, and wrote up the results of the project with collaboration with external partners.

Objective: To explore the influence of demographic factors and flourishing on workplace distractions in a cross-country analysis of Saudi Arabia and Jordan.

Methods: This cross-sectional comparative study was conducted in two government hospitals: one in eastern Saudi Arabia and the other in northern Jordan. Data were collected from the nurses using convenience sampling. The required sample size was determined using the G*Power software, with a target of 242 nurses per country, resulting in 484 participants. Ultimately, the final sample consisted of 437 nurses: 222 from Saudi Arabia and 215 from Jordan. Two online instruments were used to collect data on the distractions and flourishing.

Results: The study found that “using the Internet” and “using the phone” were the most time-consuming distractions among nurses, while “watching TV” was the least time-consuming. There were significant associations between demographics and distractions, with participants from Saudi Arabia having lower distraction scores than participants from Jordan. Younger participants were more distracted than older participants, whereas male participants were more distracted than female participants were. Smokers and individuals with less expertise exhibit higher levels of distraction. Furthermore, degree of education was associated with higher levels of distraction. Nurses in Saudi Arabia experience a much greater loss of productivity due to distractions than their Jordanian counterparts. Regression analysis revealed that experience, “Mental and Physical Health” domain scores, smoking status, and educational level all highly predicted distraction levels among Saudi Arabian and Jordanian nurses, accounting for approximately 9.6% of the differences in distraction.

Conclusion: In this cross-country study on workplace distractions among Saudi and Jordanian nurses, “using the Internet” and “using the phone” emerged as the most time-consuming distractions. Younger age, male sex, smoking, and less experience are associated with higher distraction levels. Additionally, higher education levels were linked to increased distraction. Implementing employee flourishing activities can help reduce distractions and enhance productivity. This study offers valuable insights into improving nurses’ performance and well-being.

Keywords: cross-country analysis; flourishing; Jordan; nurses; Saudi Arabia; workplace distractions

1. Introduction

Distraction is a constant challenge in fast-paced modern work environments that interferes with activities and leads to consequences, such as medical errors, conflicts, delays in treatment, and reduced healthcare productivity [1–4]. Distractions take someone's focus away from their current task [5]. Nurses must pay attention while managing a variety of tasks in a fast-paced atmosphere in order to provide high-quality care. Every action can have a different result and disastrous effects. Therefore, distractions have been extensively researched in the healthcare field [6]. Complex skills are needed to handle these disruptions because distractions can lead to nurses losing focus, which raises the possibility of patient safety problems [7, 8]. According to Sørensen and Brahe [9], nurses are frequently questioned about their work and are asked for patient information. Other healthcare professionals, nursing staff, phones, patients, family members, visitors, and self-interruptions are primary causes of distraction [9, 10]. Westbrook et al. observed 98 nurses who prepared and administered 4,271 drugs to 720 patients in an Australian hospital. According to study findings, a nurse's probability of making a medication error increased by 12.7% for every interruption, and this risk tripled when a nurse was interrupted six times [4]. According to a study by Hall et al. [11], which examined 13,025 distractions encountered by medical and surgical nurses in 36 units from nine hospitals, 90% of distraction-related errors led to treatment delays or a loss of attention or concentration. These mistakes occur frequently during paperwork, medical administration, procedures, or assessments related to patient care.

Flourishing, encompassing well-being and efficient work, plays a crucial role in employee satisfaction. It represents a state of positive health, characterized by high levels of emotional, psychological, and social well-being [12]. It encompasses happiness, resilience, commitment, and determination and contributes to overall well-being. Positive health behaviors and outcomes [13], job satisfaction [14], and optimal biomarkers of inflammation [15] have all been linked to flourishing in previous research. A recent study involving resident physicians found that flourishing was positively correlated with resilience and coping and negatively correlated with emotional exhaustion and negative affect [16]. Flourishing can help nurses overcome adversity, such as hospitalized patients who are incurable, by giving them confidence to act quickly to preserve patients' lives, hope that every patient will recover, and great optimism for patient healing [17].

Successful employees experience fewer difficulties at work, enjoy autonomy, receive better rewards, and receive more support than their less successful colleagues [18]. The work environment also influences well-being, with stimulating work promoting well-being and uninteresting environments having a negative impact on overall flourishing [19].

Interruptions that require attention, such as phone calls, differ from distractions and irrelevant inputs, which must be ignored [20–22]. An average of 86 interruptions per day

affect concentration and productivity [23]. Despite the importance of well-being, few studies have examined its relationship with distraction [24]. Internal (malaise and fatigue) and external (personal contact, emails, and calls) factors contribute to distractions and cause errors, accidents, poor work quality, stress, anger, emotional fatigue, and reduced job satisfaction and engagement [25].

Healthcare facilities, which are particularly prone to distractions, have recently received attention due to potential errors and lack of focus on important tasks [7, 8, 20]. Although previous research has examined the types of distractions, few studies have focused on nursing staff distraction costs and related variables. This study fills this gap by comparing distraction costs among Saudi Arabian and Jordanian nurses, identifying the causes, examining work-related factors, and examining the role of flourishing in reducing productivity. Demographic impacts were also examined to provide cross-national insights into improving employee well-being and healthcare efficiency. In this study, we aimed to expand the existing knowledge base in this field by examining the causes, effects, and potential mitigating variables of nursing distractions. It seeks to provide useful information that can direct practice and policy, ultimately enhancing staff well-being and patient care.

2. Methods

2.1. Site, Setting, and Design. This comparative cross-sectional study was conducted in the eastern region of Saudi Arabia and northern Jordan, specifically focusing on government hospitals that fall under the Ministry of Health (MOH). The data for this study were gathered from nurses working in various units in these hospitals. The study was conducted in a government hospital located in the Eastern Province of Saudi Arabia. This region is renowned for its diverse population and rapid urbanization, resulting in a mix of urban and rural healthcare settings. In Jordan, the data were collected from a government hospital in the northern region, which predominantly serves rural and semiurban populations. This provides valuable insights into healthcare delivery in less urbanized settings. These locations were chosen to encompass a wide range of sociodemographic characteristics and healthcare environments, thereby enhancing the generalizability of the study's findings. An age dichotomy of 40 years was chosen based on the available literature, which indicates that age 40 is a significant milestone in the careers and lifestyles of nurses. This cutoff aids in distinguishing between younger and older participants in terms of their workplace experiences and vulnerability to distractions. Experience in this study pertains to the duration that nurses have devoted to their profession, which is being considered to assess its influence on workplace distractions and productivity. BMI data were collected to explore their correlation with workplace distractions, as prior research has revealed that physical health can affect cognitive function and productivity, thus establishing BMI as a pertinent variable.

2.2. Sampling and Sample Size and Calculation. The population sample consisted of nurses, and a convenience sample was used. Nurses working in government hospitals in both countries were invited to participate in the study. This study primarily focused on governmental hospitals that fall under the purview of the MOH as they exemplify the wider healthcare system and abide by regulatory standards imposed by the MOH. The required sample size was calculated using the G*Power software, resulting in 242 nurses estimated for each country, assuming an effect size of 0.3 and alpha equal to 0.05. An additional 20% was added to account for potential nonresponse. In total, 484 nurses were recruited to ensure adequate response rates.

2.3. Instruments. Two instruments were used in the study. The first instrument focuses on distractions, gathering data on the frequency and duration of various types of distractions to discern patterns [26]. Participants reported how often they had engaged in each type of distraction in the previous week and how much time it took them to complete each distraction. The total duration for each participant was calculated by multiplying the distraction time with the frequency of each week. The participants were surveyed regarding the distractions they encountered in their workplace using a comprehensive questionnaire. For instance, one of the questions inquired, "How frequently did you experience distractions during the working day, and for how long did these distractions persist?" Participants provided specific information pertaining to the frequency and duration of distractions across a range of activities such as conversing with colleagues, utilizing the phone and Internet, scheduling personal appointments, engaging in online shopping, making bill payments, receiving visits from family or friends, taking breaks for snacks or smoking, organizing clutter, participating in gossip, extending lunch breaks, and attending meetings.

The second instrument is the Flourishing Index. There are 12 elements in each of the six domains: Happiness and Life Satisfaction, Mental and Physical Health, Meaning and Purpose, Character and Virtue, Close Social Relationships, and Financial and Material Stability. Each point was scored on an 11-point scale ranging from 0.0 to 10.0. The scores for each of the first six domains were added, with the extreme categories flagged and aligned to higher scores indicating more positive responses. High scores indicated that people had strong opinions about themselves when it came to human flourishing. The questionnaire covered various domains of well-being, with the participants rating their experiences on an 11-point scale. For instance, participants were instructed to assess their overall life satisfaction by envisioning a ladder with steps ranging from 0 at the bottom to 10 at the top, representing the best and worst possible life scenarios, respectively. The participants were also asked to evaluate their general level of happiness using the same scale. In addition, participants were asked about their perceptions of their physical health, with responses ranging from 0 to 10 [27, 28]. The survey was conducted using the online survey platform, QuestionPro (<https://www.questionpro.com>).

QuestionPro was chosen because of its user-friendly interface, secure data-handling capabilities, and proficiency in managing large-scale surveys across various geographical regions. This platform enabled us to effectively engage a broad range of nurses in Saudi Arabia and Jordan, thereby ensuring a rigorous and uniform data collection process. Furthermore, QuestionPro's functionalities, including real-time data analytics and customizable survey templates, have facilitated extensive data management and analysis. The survey was conducted in Arabic.

2.4. Pilot Study. Two key pilot studies were conducted to assess the questionnaire's construct validity in different settings. In a Jordan pilot study involving 40 nurses, Pearson's correlation analysis identified questions as valid if their R value exceeded 0.3120, as determined by the critical score table. Improvements in the participants' clarity were made through careful adjustments to two negligible points. The internal consistency assessment conducted using Cronbach's alpha analysis highlighted robust coherence, with an r value between 0.411 and 0.785 and a commendable Cronbach's alpha coefficient of 0.825. Likewise, the Saudi pilot study involving 27 nurses relied on Pearson correlation analysis for item construct validity. Questions were considered valid if their R value exceeded 0.381, based on the cutoff value of the correlation analysis table. The results were both meaningful and valid and were confirmed by reliable Cronbach's alpha analysis, with r values ranging from 0.524 to 0.866, yielding a remarkable Cronbach's alpha coefficient of 0.9224 [29]. Both pilot studies confirmed the questionnaire's construct validity and provided valuable insights into its clarity and cultural appropriateness. Minor adjustments were made based on participant feedback and quantitative analysis to improve clarity and relevance. The measures of distraction used in this study were specifically developed to address the gaps identified in the literature, and the detailed rationale for their development and psychometric testing procedures is included in the revised manuscript. These refinements ensured that the questionnaire is robust and culturally relevant to the main study.

2.5. Ethical Consideration. The study protocol was approved by the Institutional Review Board of Imam Abdulrahman Bin Faisal University in Saudi Arabia (IRB-2022-04-275) and Al al-Bayt University in Jordan (Protocol no. 10/2021/2022). The participants were informed about the purpose, significance, and benefits of the study and provided with an information sheet. The participants emphasized that their involvement was voluntary and that there would be no physical or mental harm incurred from the study. Informed consent was obtained from all the participants. The collected data were treated as confidential, and the research team was solely responsible for its management.

2.6. Cost Analysis. The cost analysis conducted in this study aimed to examine lost productivity, which was measured by calculating the average minutes lost per week per nurse for

each distractor. Two measures, the mean and interquartile range (IQR), were used to represent the distribution of lost minutes. The mean provided an average estimate of the time lost, while the IQR captured the central spread of the data, offering a robust measure of the central tendency that was less affected by outliers. The lost minutes per nurse were then multiplied by the pay per minute for each nurse in both countries, resulting in monetary loss. By quantifying the time spent on distractors, the calculation of productivity loss allows for the direct conversion of time loss into monetary amounts. This approach provides a practical perspective on the economic impacts of distractors. To evaluate the cost implications of workplace distractions, economic calculations incorporated the reported time allocated to distractions and the average wage rates for nurses in each country. The economic impact was determined by estimating the monetary value of productivity loss.

2.7. Data Analysis. Data were stored and analyzed using SPSS version 22. Microsoft Excel was used to calculate the cost of the lost productivity. Continuous data are presented as means and standard deviations, while categorical variables are presented as frequencies and percentages. The internal consistency of the scales used in this study was tested using reliability analysis, and Cronbach's alpha coefficients were calculated. Independent *t*-tests and ANOVA were used to determine differences between groups. Pearson's correlation coefficients were used to assess the relationships between variables. Multiple linear regression was used to predict the cost of the distractions. Statistical significance was set at *p* of less than 0.05.

2.8. Validity and Reliability. The study had a total response rate of 53.1% in both countries. Of the initial sample of 484 invited participants (242 from each country), 437 nurses completed the surveys. Specifically, 222 nurses from Saudi Arabia and 215 from Jordan participated in this study. Nineteen participants were excluded from the analysis due to missing data, with one participant from Saudi Arabia and 18 from Jordan being affected. Additionally, 18 participants were excluded owing to a lack of variance, and eight participants with more than 20% missing data were removed to prevent bias. Imputation filled the gaps for variables with values less than 20%. The alpha value (0.678–0.918) confirmed the internal consistency of the scale. Three outliers were identified using Mahalanobis distances, eliminated at the 5% significance level, and influence integrity was preserved. After these steps, the final sample size for the analysis was 437 participants to increase the reliability. Transformations ensured the normality of the dependent variables. Validation of the distraction and flourishing scales using Pearson's correlation showed significant relationships ($p < 0.001$), confirming the robustness and reliability of the study in subsequent statistical analyses.

3. Results

The study had an overall response rate of 53.1%, with 437 participants completing the survey. Of these, 222 were from

Saudi Arabia and 215 were from Jordan. The majority of the participants were 40 years old (80.8%), female (79.2%), and nonintensive care professionals (73.2%) and had 20 years of experience (87.4%). The proportion of nonsmokers was 79.4%, 70.3% were married, 43.7% had a diploma, and 47.1% had a BSc degree. The BMI distribution was 2.1% underweight, 36.6% normal weight, 38.7% overweight, and 22.7% obese. These demographic data provided valuable insights into the composition of the participants and improved our understanding of the study results (Table 1).

3.1. Cronbach's Alpha. Cronbach's alpha coefficient of the flourishing scale was 0.896, indicating a high level of internal consistency. A total of 437 participants were included in this study, with 50.8% from Saudi Arabia and 49.2% from Jordan.

Table 2 shows the data on various distractions and weekly time lost by nurses. The highest average minutes lost occurred when using the Internet (mean = 62.9), followed by telephone (mean = 50.6), and the least when watching television (mean = 9.5). The total distraction category showed that nurses lost an average of 378.9 min to distractions, with a median of 194.0 min.

Table 3 highlights the notable differences in distraction levels between participants from Saudi Arabia and Jordan in the different categories. Participants from Saudi Arabia reported lower total distractions (mean = 308.6) than those from Jordan (mean = 455.2), indicating a significant disparity in the total distracted experiences ($p = 0.014$). In particular, there was a significant difference in the occurrence of smoking/snacking breaks between the two groups. Participants from Saudi Arabia (mean = 14.1) reported significantly fewer distractions in this category than did participants from Jordan (mean = 33.9, $p = 0.001$). These results suggest that people from Saudi Arabia generally experience fewer distractions and take fewer smoke/snack breaks than their Jordanian counterparts.

The lost productivity of all nurses in Saudi Arabia due to all types of distractions was estimated at 308.6 min per week. This equates to a monetary loss of 84.22947 USD per week, considering a payment rate of 0.2223 USD per minute. Likewise, the lost productivity for all nurses in Jordan due to all types of distractions was calculated at 455.2 min per week. This equates to a monetary loss of 40.33072 USD per week with a payment rate of 0.0886 USD per minute.

Table 4 shows the demographic influences of the distractions. Participants from Saudi Arabia had a lower average distraction score (308.6) than their Jordanian counterparts (455.2) ($p = 0.014$). Age under 40 years correlated with a higher mean distraction score (444.6) than age over 40 years (113.8) ($p = 0.001$). Men had a higher average distraction score (523.3) than women (343.4) ($p = 0.015$). Experience under 20 years was associated with a higher mean distraction score (426.9) than experience over 20 years (62.1) ($p = 0.001$). Smoking status influenced distractions: Nonsmokers scored 342.4, while smokers had a higher average score of 529.0 ($p = 0.012$). Differences in educational levels were evident; those with a diploma scored 277.9

TABLE 1: Demographic characteristics of participants.

Variable	Category	Frequency	Percent
Residency	Saudi	222	50.8
	Jordan	215	49.2
Age	≤ 40	353	80.8

	Overweight	169	38.7
	Obesity	99	22.7

TABLE 2: Type of distraction and minutes loss per week among nurses.

Type of distraction	Mean (SD)	Median (IQR)	Minimum	Maximum
Use the Internet	62.9 (155.7)	15.0 (44.5)	0	961
Use the phone	50.6 (131.3)	12.0 (32.0)	0	961
Discussions with coworkers, patients, or work acquaintances	31.4 (84.7)	12.0 (26.0)	0	961
Meeting	25.7 (82.6)	4.0 (21.0)	0	961
Clutter	25.0 (89.5)	2.0 (15.0)	0	961
Smoke and snack breaks	23.8 (61.1)	6.0 (24.5)	0	961
Gossip	22.5 (100.7)	1.0 (11.0)	0	961
Organizing and planning for personal time	20.6 (37.2)	9.0 (21.0)	0	341
Daydream	19.6 (79.7)	1.0 (9.5)	0	930
Taking too long of a lunch with colleagues	18.9 (57.6)	2.0 (21.0)	0	961
Pay personal bills	17.8 (79.7)	2.0 (8.0)	0	961
Shop from work by catalog, phone, or Internet	16.3 (55.0)	1.0 (11.0)	0	961
Play computer games	12.9 (74.1)	1.0 (3.0)	0	961
Leisure reading (e.g., books and magazines)	10.8 (50.0)	1.0 (5.0)	0	961
Visits at work from family, friends, or others	10.4 (24.2)	1.0 (7.5)	0	248
Watch TV	9.5 (25.8)	1.0 (4.0)	0	248
Total distractions	378.9 (638.0)	194.0 (324.5)	0	6315

points, BSc holders scored 436.6, and MSN or PhD holders scored the highest at 586.9. There was a significant difference in the distraction scores between graduates and college graduates ($p = 0.004$).

The analysis found that age was a significant factor affecting flourishing scores, with those aged 40 years and younger having lower average scores in the areas of Happiness and Life Satisfaction, Mental and Physical Health, and Meaning and Purpose ($p = 0.023$, $p = 0.024$, and $p = 0.022$). Conversely, those over 40 years of age tended to have a higher level of prosperity. Gender-specific scores in the Mental and Physical Health domains ($p = 0.012$) indicated sex differences in flourishing. Experience also played a role;

participants over 20 years of age showed higher scores in all areas ($p = 0.002$, $p = 0.018$, $p = 0.028$, and $p = 0.001$), indicating increased flourishing with greater experience. However, education level, smoking habits, marital status, type of specialty, and body mass index did not show any significant influence on the level of success. No significant differences were observed between graduate and college graduates, smokers and nonsmokers, marital status, discipline, or body mass index categories, implying limited or negligible effects on overall flourishing behavior (Table 5).

Table 6 shows the correlations between the amount of distraction in minutes per week and different domains of flourishing. These correlations provide insight into the

TABLE 3: The difference in distraction between Saudi and Jordan.

Distraction/country	Saudi Mean (SD)	Jordan Mean (SD)	95% CI	Sig
Discussions with coworkers, patients, or work acquaintances	37.9 (115.2)	24.6 (29.1)	(-2.4, 29.0)	0.096
Use the phone	49.9 (140.1)	51.3 (122.0)	(-26.1, 23.4)	0.916
Use the Internet	74.8 (191.8)	50.6 (105.5)	(-4.8, 53.2)	0.102

	> 20	62.1 (647.9)		
Smoking	No	342.4 (634.4)	(-331.3, -42.0)	0.012
	Yes	529.0 (571.4)		
Marital status	Single	508.7 (578.9)	(395.6, 621.9)	0.056
	Married	344.8 (633.3)	(273.7, 415.9)	
	Divorce or widowed	301.1 (669.9)	(30.5, 571.7)	
Educational level	Diploma	277.9 (639.3)	(186.7, 369.2)	0.004 ^a
	BSc	436.6 (610.5)	(352.6, 520.7)	
	MSN or PhD	586.9 (562.0)	(407.2, 766.7)	
BMI	Underweight	289.8 (209.1)	(129.1, 450.6)	0.542
	Normal	423.1 (614.9)	(326.8, 519.4)	
	Overweight	386.9 (599.8)	(295.8, 478.0)	
	Obesity	311.2 (706.9)	(170.2, 452.2)	

^aTukey HSD: diploma versus BSc ($p = 0.030$); diploma versus MSN or PhD ($p = 0.012$).

strength and direction of the relationships between these variables. These results suggest a moderately negative association between distraction and several flourishing domains. In particular, higher levels of distraction correlated significantly with lower levels of flourishing in the Happiness and Life Satisfaction domains ($r = -0.172$, $p = 0.001$), Mental and Physical Health domains ($r = -0.202$, $p = 0.001$), and Close Social Relationships domains ($r = -0.142$, $p = 0.003$). However, the correlations between distraction and the Meaning and Purpose ($p = 0.112$), Character and

Virtue ($p = -0.456$), and the Financial and Material Stability ($p = -0.313$) domains were not statistically significant.

The model summary showed that approximately 9.6% of the distraction variation was explained by predictors, accounting for approximately 10.4% of the differences. The Durbin-Watson statistic (1.858) suggests no systematic errors in the predictions. The ANOVA table shows the statistical significance of the model ($F = 12.537$, $p < 0.001$), indicating that the predictors collectively influenced distraction. Stepwise regression identified significant predictors

Sig	-0.001	-0.001	-0.112	-0.456	-0.003	-0.313

Note: Domain 1: Happiness and Life satisfaction, Domain 2: Mental and Physical Health, Domain 3: Meaning and Purpose, Domain 4: Character and Virtue, Domain 5: Close Social Relationship, and Domain 6: Financial and Material Stability.

including experience (negative association, $p = 0.001$), mental and physical health (inverse association, $p = 0.001$), smoking (positive association, $p = 0.020$), and educational level (higher levels associated with distraction, $p = 0.025$). In summary, experience, mental/physical health, smoking, and education predicted distraction, with more experienced, healthier, and better-educated participants as well as smokers exhibiting varying levels of distraction (Table 7).

4. Discussion

This study aimed to explore the impact of demographic factors and flourishing on workplace distraction among nurses in Saudi Arabia and Jordan. The results demonstrated that “using the Internet” and “using the phone” were the most time-consuming distractions, consistent with previous research that has identified these as common sources of interruption in healthcare settings [7, 30]. The extensive utilization of technology in contemporary healthcare, although crucial for communication and information management, also poses significant challenges. These distractions have the potential to disrupt the workflow, diminish efficiency, and compromise patient safety by diverting attention away from critical tasks.

The demographic analysis revealed that younger, male, and less experienced nurses, as well as those who smoked, reported higher levels of distraction. These findings are consistent with previous studies that indicate that younger and less experienced nurses may be more susceptible to distractions due to a lack of developed coping strategies and greater reliance on technology for both work-related and personal tasks [7]. The increased levels of distraction among male nurses may be attributed to varying stress responses or social factors that influence their interactions with technology. Smoking, often used as a coping mechanism for stress, appears to be associated with higher levels of distraction, suggesting that nurses may be more inclined to take breaks or divert their attention during work hours.

An association between educational level and distraction was observed, with nurses with higher education levels reporting a greater incidence of distraction. This correlation can be attributed to the heightened cognitive demands placed on nurses with advanced education, who frequently undertake additional responsibilities necessitating multi-tasking, thereby augmenting their vulnerability to potential distractions. These findings highlight the intricate nature of the nursing work milieu, wherein personal attributes and professional obligations interact to shape the degree of distraction experienced.

The cross-country comparison conducted in this study revealed that despite reporting fewer distractions overall,

Saudi nurses encountered a more significant decrease in productivity than their Jordanian counterparts. This finding, which seems contradictory, implies that, although Saudi nurses may be more skilled in limiting the number of distractions, the distractions they encounter may have a more profound influence on their workflow. This outcome can potentially be ascribed to cultural or systemic factors within the Saudi healthcare system that exacerbate the effects of distractions such as increased workloads or more stringent performance expectations. Conversely, Jordanian nurses may employ more effective strategies to manage distractions, resulting in lower perceived impact on productivity.

The finding regarding the substantial influence of flourishing, specifically on both mental and physical well-being, in predicting distraction levels is essential. Nurses who exhibit better health reports experience fewer distractions, emphasizing the crucial role of well-being in sustaining concentration and productivity. This observation is in line with previous research which indicates that fostering mental and physical health within the workplace can heighten employee performance and decrease the occurrence of errors [31, 32]. Consequently, initiatives designed to promote flourishing, such as stress management programs, mindfulness training, and activities promoting physical wellness, hold significant potential for mitigating the detrimental effects of distractions and ultimately enhancing overall nurse performance.

These findings have important implications for patient safety. It is well established that distractions in healthcare settings increase the risk of errors, which can ultimately lead to grave consequences for patient outcomes [4]. Through the identification of pivotal predictors of distraction, this study offers valuable insights into the development of targeted interventions with the objective of minimizing distractions. For instance, training programs that bolster coping skills among younger and less experienced nurses, as well as initiatives that foster healthy lifestyles and stress management, hold promise in this regard.

The cultural disparities observed between Saudi and Jordanian nurses underscore the need to employ context-specific methodologies to effectively address workplace distractions. Interventions should be customized to account for the distinctive cultural and systemic elements that shape nursing practices in each country. For instance, strategies that demonstrate efficacy in Jordan may require adaptation to align with the distinct work environments prevalent in Saudi Arabia.

In conclusion, this study contributes to academic knowledge on the correlation between demographic factors, flourishing, and workplace distractions in the nursing work

TABLE 7: Regression analysis results for predicting distraction.

Predictor	B	SE	β	Sig	R ²	F	Adj R ²
Intercept	927.734	111.356	—	0.001	0.104	12.537	0.096

environment. The findings indicate that mitigating distractions has the potential not only to enhance the well-being and performance of nurses but also to promote patient safety. Further research should focus on studying the long-term effects of these distractions and evaluating the efficacy of different intervention strategies across various healthcare settings. By addressing these challenges, healthcare systems can provide better support to nursing staff, ultimately resulting in improved quality of care and patient outcomes.

This study had several limitations. The study's use of a specific hospital sample in Saudi Arabia and Jordan restricts the generalizability of the findings to other regions or healthcare settings. Convenience sampling may introduce selection bias, as participants may not adequately represent the broader nursing population. The reliance on self-reported data introduces a response bias, which may result in inaccuracies due to social desirability or recall issues. Additionally, the cross-sectional design does not allow for causal inferences, capturing only a single point in time and limiting the establishment of temporal relationships. By focusing solely on nurses, the applicability of the results to other healthcare professionals or industries is limited.

The assumptions made in an economic analysis of productivity loss may oversimplify the complex factors that influence workplace efficiency, potentially distorting impact estimates. Furthermore, the exclusion criteria and removal of outliers, although necessary, may have introduced bias by excluding data that may have influenced the results. Finally, the instruments used, while validated, may not fully capture the cultural nuances or specific workplace challenges faced by nurses in different countries. Despite these limitations, this study offers valuable insights into workplace distractions among nurses, thus informing future research.

5. Nursing Implications

Understanding the factors that hinder the influence of demographic factors and flourishing on workplace distractions among nurses in Jordan and Saudi Arabia will assist policymakers in both countries, governments, NGOs, and other stakeholders in creating targeted policies and programs. These initiatives will prepare an appropriate work environment and help reduce sources of workplace distractions. Healthcare organizations should manage their cell phone usage to minimize distractions by establishing effective and practical usage policies. Additionally, we recommend

orientation programs for novice nurses that tailor behaviors to reduce workplace distractions, including smoking and frequent cell phone use. In addition, we recommend the implementation of policies that restrict cell phone use in clinical settings.

6. Conclusions

This study sheds light on the critical impact of nurse distractions on well-being, including happiness, mental and physical health, and social relationships. Factors such as age, sex, experience, smoking, and education have a significant influence on these distractions. Our findings underscore the economic ramifications of nurse distraction in Saudi Arabia and Jordan. Regression analysis identified experience, health status, smoking, and education as the key predictors of distraction levels. Despite limitations, such as convenience sampling and potential self-report bias, our results provide valuable insights into the adverse effects of nurse distractions and their economic implications. This study emphasizes the necessity for targeted interventions and policies to mitigate distractions and enhance nurses' well-being. Future research should investigate the longitudinal effects of these distractions and assess the effectiveness of specific interventions in diverse healthcare settings.

Aim: To empirically investigate the impact of ethical leadership on nurses' moral courage in China and examine the mediating role of psychological empowerment in this relationship.

Background: Moral courage is essential for alleviating nurses' moral distress, safeguarding patients' safety and rights, and providing high-quality care. Previous studies have emphasized the strong relationship between ethical leadership and moral courage; however, little is known about the actual impact of ethical leadership on nurses' moral courage. This study introduces psychological empowerment, sets out to test empirically its role in the relationship between ethical leadership and moral courage, and provides countermeasures and a theoretical basis for cultivating nurses' moral courage.

Methods: Between February and May 2023, a questionnaire survey was conducted among 837 nurses from five hospitals in Sichuan Province, southwest China. The three validated self-report scales, the ethical leadership scale, psychological empowerment scale, and nurses' moral courage scale, were used to collect data. We used IBM SPSS 27.0 for descriptive statistics, univariate analyses, Cronbach's α , and correlations of each variable, modeling a hypothesized model of ethical leadership on moral courage in nurses and testing the internal mechanisms by AMOS 26.0.

Results: Ethical leadership significantly positively correlated with psychological empowerment ($r=0.374$, $p < 0.01$), as well as moral courage ($r=0.341$, $p < 0.01$). In addition, psychological empowerment significantly positively correlated with moral courage ($r=0.518$, $p < 0.01$). The structural equation modeling (SEM) shows a satisfactory model fit: $\chi^2 = 2156.36$, $df = 849$, $\chi^2/df = 2.540$, root mean square of approximation = 0.043, standard root mean square residual = 0.047, normed fit index = 0.911, Tucker–Lewis index = 0.941, and comparative fit index = 0.944. Ethical leadership directly influenced moral courage ($\beta = 0.135$, $p = 0.006$) and indirectly affected moral courage via psychological empowerment ($\beta = 0.247$, $p = 0.001$).

Conclusion: Promoting ethical leadership and psychological empowerment is essential for nurses to promote moral courage. The results of this study illustrate the pivotal role of psychological empowerment in establishing the impact of ethical leadership on nurses' moral courage and the partially mediating part of psychological empowerment in this relationship.

Implications for Nursing Management: Nursing managers should understand the importance of moral courage in protecting patients' rights and interests, as well as in maintaining a stable nursing workforce. They should reinforce the positive influence of ethical leadership and embrace an ethical leadership style. In addition, providing relevant training to enhance nurses' psychological empowerment will help cultivate moral courage among them.

Keywords: ethical leadership; moral courage; nurses; psychological empowerment

1. Introduction

As direct providers of healthcare services, nurses play an essential role in maintaining human health and the development of healthcare. In 2023, the National Health Commission of China has clearly emphasized the need to improve nursing services, ensure nursing quality and safety, and safeguard people's health rights and interests [1]. From a humanist perspective, nursing is an ethical practice that requires nurses to have the courage to take a moral stance and remain confident in what they believe is right. However, due to the complexity of the clinical environment and other issues, as with some other developing countries [2, 3], Chinese nurses often encounter ethical dilemmas with hospital organizations, managers, colleagues, and patients, such as limited human resources, staffing insufficient to provide quality care to patients, provide "active care" to patients that have no therapeutic effect or does not remove the patient from life support dependency, some ethical dilemmas of care due to patients' financial constraints, and the malpractice of physician and colleague, which are making them in ethical dilemmas, generating negative emotions and burnout, and even hindering the development of the healthcare system [4]. Previous research has shown that nurses with moral courage are better able to deal with ethical issues and experience fewer ethical dilemmas [5] and have the ability to overcome their weakness of will when faced with situations that conflict with their professional values to take action to face ethical challenges head-on. Accordingly, studying the moral courage of nurses is of great significance in improving the quality of nursing services and safeguarding patients' rights and interests.

2. Literature Review

Moral courage is recognized globally as crucial to promoting patient safety and ethical care [6], and the core is safeguarding patients' rights [7]. As a fundamental virtue, moral courage refers to a nurse acting under pressure and following their work situation and professional orientation, taking responsibility for decision-making without fear of danger, and rational acting despite expected adverse consequences [8]. Moral courage plays a pivotal role in improving the psychological resilience of nurses and the patient's quality of life [9]. It inspires nurses to advocate for patients when their rights are threatened [10]. The main personal characteristics of nurses' moral courage include moral integrity, acting according to one's conscience, accountability, and self-actualization [8]. Previous studies on moral courage focus on measuring its levels and comparison across groups such as gender, age, educational status, and education related to medical ethics [9, 11], these do not address the mechanisms that influence moral courage. Further studies found that nurses rated their moral courage as high and considered themselves morally courageous but found it difficult to be truly courageous when faced with ethical dilemmas in practice, and still needed support from their organizations and superiors [9]. Organizational factors have been identified as influences on nurses' moral courage

[12]; however, leadership as an essential factor in organizational contexts has rarely been explored.

Brown defines ethical leadership as demonstrating normatively appropriate conduct through personal actions and interpersonal relationships and promoting such behavior to followers through two-way communication, reinforcement, and decision-making [13]. In the field of nursing, nursing managers with ethical leadership support the development of moral competence in nurses as pioneers in the nursing profession who are role models for nurses and their behaviors will influence the ethical conduct of nurses [14]. Ethical leadership attempts to create and maintain a favorable ethical climate in the work environment [15]. It is thought to be an effective leadership style in nursing management. Combing through the relevant literature revealed that studies exploring ethical leadership in nursing have yielded positive results. A study by El-Gazar et al. has shown that psychological safety mediated the link between ethical leadership and nurses' internal whistleblowing intentions, and nurse leaders can foster nurses' intentions to blow the whistle internally by adopting ethical leadership behaviors and enhancing psychological safety among nurses [16]. In addition, nurses with a high level of flourishing and who work with a manager exhibiting ethical leadership behavior are more likely to activate extra-role behavior to go the extra mile in their jobs [17]. However, moral courage, a well-recognized virtue in nursing, has not yet been the subject of a study focusing on the positive effects of ethical leadership on nurses' moral courage in the context of Chinese culture. Therefore, it is necessary to conduct this study to fill the gap in existing research and provide a basis for exploring the theory of intervention strategies for moral courage.

Psychological empowerment is the psychological condition or cognitive sense of being empowered that individuals experience in a specific work situation, which reflects the individual's positive attitude toward their work role [18]. Job meaning, competence, self-efficacy, and impact are the four parts of psychological empowerment that make up an individual's intrinsic motivation to work [19]. Studies have shown that nurses who have higher psychological empowerment can enhance innovative behavior [20], increase job satisfaction [21], and reduce ethical conflicts at work [22]. Moreover, the psychological condition of nurses is also an important factor affecting patient satisfaction [23]. According to previous research reports, Khoshmehr et al. [24] found that the relationship between psychological empowerment and moral courage positively correlates with nurses having a higher level of psychological empowerment and showing more courage in the face of internal fears [25]. In addition, there is a positive relationship between ethical leadership and psychological empowerment [26, 27]. In other words, ethical leadership enables employees to experience meaningful job roles throughout their careers. Although the results of previous studies have confirmed the two-by-two correlation between ethical leadership, psychological empowerment, and moral courage in nurses, no studies have been conducted on the coordinated role of ethical leadership and psychological empowerment together

on moral courage in nurses and the mechanism of psychological empowerment in ethical leadership and moral courage in nurses has not been explored.

3. Theoretical Framework and Hypotheses

Social learning theory [28] states that personal behavior, especially more complex behavior is learned primarily by observing or imitating the behavior of others. The theory stresses the importance of individual cognition in the learning process and the interconnectedness of cognition and the environment in influencing individual learning to produce or change a behavior. In this study, ethical leadership focuses on ethics, as a leader and role model for nurses, treating nurses with respect and fairness, not only being ethical people themselves but also creating a work environment with an ethical atmosphere for nurses [29], which is an organizational situational factor to which individuals belong; psychological empowerment brings nurses a deeper level of psychological cognition, reflecting the process of personal growth and development, which is the cognitive feeling of individuals in the work environment. Nurses with moral courage dare to speak out for the rights, safety, and justice of patients in the face of conflicts and unfavorable situations that arise in nursing practice [30], which is considered to be an essential characteristic and ethical behavior that nurses should possess.

According to Thomas and Velthouse [31], employee psychological empowerment is shaped and influenced by the work contexts, such as leaders and leaders' behavior. Based on the social learning theory, when nurses feel stimulated by the nurse manager and perceive the role as trustworthy, they are more likely to build up their psychological perceptions and gain psychological empowerment in work by observing and mimicking the attitudes and behaviors of the nurse manager. When nurses have psychological empowerment at work, they are more courageous to take practical actions to face and deal with some ethical issues in their daily work, which positively affects their moral courage. Therefore, based on the social learning theory and other relevant literature reviewed above, this study explores the potential mechanisms among ethical leadership, psychological empowerment, and nurses' moral courage. We propose the four hypotheses as follows:

1. Hypothesis 1: Ethical leadership is positively related to psychological empowerment.
2. Hypothesis 2: Psychological empowerment is positively related to moral courage.
3. Hypothesis 3: Ethical leadership is directly positively related to moral courage.
4. Hypothesis 4: Psychological empowerment mediates the association of ethical leadership with moral courage.

4. Methods

4.1. Study Design. This cross-sectional study was part of a project aimed at revealing the relationship between ethical leadership, spiritual climate, psychological empowerment,

nurse-patient relationship, and nurses' moral courage. A previous article reporting on the relationship between spiritual climate and the psychological empowerment of nurses in China has been published [32]. This article reports findings on the impact of ethical leadership on nurses' moral courage and examines the mediating role of psychological empowerment in this relationship.

4.2. Participants and Setting. Sichuan Province is located in the southwestern interior of China and consists of 5 regions: East Sichuan, South Sichuan, West Sichuan, North Sichuan, and Central Sichuan. As reported by Wang et al. [32], a questionnaire survey was conducted from February to May 2023 using the convenience sampling method among registered nurses in five hospitals selected from these five regions, all of which were tertiary care public hospitals with more than 1500 beds. All nurses were from different departments, including internal medicine, surgery, obstetrics and gynecology, pediatrics, emergency, and intensive care unit (ICU). The structural equation model (SEM), with a sample size of at least 200, was recommended [33], or 10 times the number of variables. The number of observed variables for this study was 18; thus, a sample size of 837 nurses aligned with the above rules. The study inclusion criteria for nurses were (1) registered nurses, (2) having at least 1 year of nursing in the current hospital, and (3) voluntary participation in this study. The criteria excluded nurses who were (1) not directly involved in patient care, such as on sick or personal leave and (2) nursing managers at the level of the head nurse and above.

4.3. Measurements

4.3.1. Nurse Demographic Characteristics. The research team designed its questionnaire on the demographic characteristics of nurses by reviewing the literature and questioning experts, which included gender, age, work department, years of working, education level, employment type, professional title, training in medical ethics (yes/no), and marital status items.

4.3.2. Ethical Leadership Scale (ELS). The ELS was created by Brown et al. [13] and designed to measure ethical leadership from nurses' perspectives. Bian [34] translated it into Chinese and validated it. The scale is single-dimensional and consists of 10 items. An example item is "My head nurse sets an example of how to do things correctly regarding ethics." Each item evaluates from "strongly disagree = 1" to "strongly agree = 5" with a five-point scale. The total scores on the scale ranged from 10 to 50. High scores indicate high levels of ethical leadership of the head nurses from the nurses' perspective. Cronbach's alpha coefficient for the original scale was 0.95 and 0.925 in this sample.

4.3.3. Psychological Empowerment Scale. The PES, a measure of psychological empowerment, was developed by Spreitzer [18], translated into Chinese, and validated by Sun et al. [35].

The scale contains 12 items with four subscales, including job meaning (3 items), job competence (3 items), self-efficacy (3 items), and job impact (3 items). An example item is “I am confident in my ability to do well in all aspects of my job.” Each item measures “*strongly disagree* = 1” to “*strongly agree* = 5” on a five-point scale. The total scores on the scale ranged from 12 to 60. High scores indicate high perceived psychological empowerment by nurses. Cronbach’s alpha coefficient of the four subscales of the original scale was in the range of 0.72–0.86 and 0.830–0.935, respectively, in this sample.

4.3.4. Nurses’ Moral Courage Scale (NMCS). The NMCS measures nurses’ moral courage. The original scale of NMCS was developed by Numminen et al. [8]. Wang et al. [36] after obtaining authorization from the authors of the original scale strictly followed Brislin’s two-person translation-back-translation model for the Chinese version of the NMCS. Five experts (one professor of nursing, three clinical nursing experts, and one professor of psychology) were hired to culturally adapt the Chinese version of the NMCS to make it suitable for the cultural environment of China and to assess its content validity to form the Chinese version of the NMCS. The Chinese version of the NMCS is consistent with the original scale and includes 21 items of four subscales, including moral integrity (7 items), commitment to good care of patients (5 items), compassion and authentic presence with the patient (5 items), and moral responsibility (4 items). Each item measured from “*does not describe me at all* = 1” to “*describes me very well* = 5” on a five-point scale. The total scores on the scale ranged from 21 to 105. High scores indicate high levels of nurses’ moral courage. Cronbach’s alpha coefficient of the four subscales of the original scale was in the range of 0.778–0.902 and 0.866–0.907, respectively, in this sample.

4.4. Ethical Consideration. The study was approved by the Ethics Committee of the Sichuan Provincial People’s Hospital, University of Electronic Science and Technology of China, the first author’s institution. Researchers explained the research’s aim, significance, and precautions to all participants and distributed the questionnaire only after receiving each participant’s informed consent. All data collected were anonymized, and the results of the completed questionnaires were not visible to anyone other than the researcher and the respondents themselves and were used only for the study.

4.5. Data Analysis. The descriptive statistics, univariate analyses, Cronbach’s α , and correlations of each variable used the IBM SPSS 27.0 (IBM, New York, NY, USA) to analyze, using frequency and percentage for count data and mean \pm standard deviation ($M \pm SD$) for normally distributed measures. Pearson’s coefficient was used to examine the correlations among ethical leadership, psychological empowerment, and nurses’ moral courage, modeling a hypothesized model of ethical leadership on moral courage in

nurses and testing the internal mechanisms by AMOS 26.0 (IBM, New York, NY, USA). The bootstrapping procedure of 5000 resamples tested the significance of the mediating effects model, and the 95% confidence interval without zero considered the mediating effect significant. Differences are two-sided, and a p value below 0.05 is considered statistically significant.

5. Data Collection

We used paper-based questionnaires for our survey. First of all, we contacted the director of the nursing department of each investigated hospital, explaining in detail the purpose, significance, and content of this study’s survey. After obtaining the consent, the nursing department of the investigated hospitals arranged for one person in charge to dock with the researchers. Then, the researchers used a unified instruction to inform the people in a ward of the investigated hospital about this study’s purpose, significance, data collection methods, and quality control methods. Finally, the researchers sent the nurses a paper version of the questionnaire to fill in. The questionnaires were filled out during each department’s morning shift or group meeting and collected on the spot after completion. Respondents involved in questionnaire completion were (1) informed that participation was voluntary and that they could withdraw at any time without reason; (2) the study was anonymous and the results of questionnaire completion would not be seen by coworkers, leaders, etc.; and (3) the survey information obtained was to be used only for nursing study. In total, 851 nurses completed and returned the questionnaires, of which 14 questionnaires were dropped from the analysis due to incomplete completion, and 837 valid questionnaires were analyzed (response rate: 98.35%).

6. Results

6.1. Demographic Characteristics of Nurses and the Univariate Analyses of Nurses’ Moral Courage. Among 837 nurses, 94.1% were female, 80.9% had a bachelor’s degree, 30.7% had a work experience of 6–10 years, and 69.2% were married. In addition, univariate analyses showed significant differences in gender, age, departments, years of working, professional titles, and training in medical ethics (yes/no) and marital status showed significant differences in nurses’ moral courage scores. The details are given in Table 1.

6.2. The Score of Nurses’ Moral Courage in the Current Study. The total scores ($M \pm SD$) of nurses’ moral courage in Sichuan Province, southwest China, was 80.68 ± 12.04 , which is mainly moderate to high, and the scores of subscales are detailed in Table 2.

6.3. Correlations for Variables of the Study. Pearson’s correlation analysis showed that ethical leadership and psychological empowerment were positively correlated ($r = 0.374$, $p < 0.01$), as were moral courage ($r = 0.341$, $p < 0.01$). In addition, positive correlations between

psychological empowerment and moral courage can be found ($r = 0.518$, $p < 0.01$), and the relationships between each scale subscale are detailed in Table 3.

6.4. SEM of Study Variables. As shown in Table 4, the model offers a satisfactory model fit: $\chi^2 = 2156.36$, $df = 849$, $\chi^2/df = 2.540$, $RMSEA = 0.043$, $SRMR = 0.047$, $NFI = 0.911$,

$TLI = 0.941$, and $CFI = 0.944$, and all indicators met the requirements. As shown in Figure 1 and Table 5, the mediating effect value of psychological empowerment is 0.247, which accounts for 64.8% of the total effect value of 0.381. Psychological empowerment partially mediates the relationship between ethical leadership and nurses' moral courage.

7. Discussion

This study explored the relationship among ethical leadership, psychological empowerment, and moral courage from nurses' perspectives, established the impact of ethical leadership on nurses' moral courage, and examined the partially mediating role of psychological empowerment in this relationship. To the best of our knowledge, this study is the first to investigate these associations and explore the potential mechanisms.

The findings of this study showed that the total scores of moral courage in nurses are moderate to high, which is analogous to other studies [37, 38]. It indicates that despite the complex and challenging healthcare environment, nurses are willing to provide good nursing care to patients and advocate for protecting their rights and interests. In this study, the highest score (3.99 ± 0.72) for moral responsibility indicated that nurses possess essential ethical qualities and can deal with ethical challenges at work with practical actions. The sample of nurses in this study were all from public tertiary-level hospitals in Sichuan Province, which, along with the high-quality development of public hospitals, requires nurses to possess professional knowledge and the ability to provide optimal solutions for patients when they face compromised rights and interests. The lowest commitment to good care of patients score (3.73 ± 0.78) indicates that in practice, nurses may compromise on protecting the rights of patients and remain silent on ethical issues that arise in the care process, and the reasons for this may be analyzed to be related to insufficient training in this area, lack of supportive managers, fear of adverse consequences due to the fear of risk-taking and bullying, and loss of job [39]. Moral courage as a moral virtue enables nurses to make the right decisions and behaviors when faced with ethical distress and helps nurses deal with ethical challenges with aplomb [40]. It is recommended that hospitals and administrators create a work environment that promotes teamwork and respectful communication. Clinical nurses should practice a "patient-centered" orientation, have solid nursing expertise and skills, understand their realities, and provide nursing care and services guided by evidence-based practice theories and nursing quality standards. Only then is it possible to gain the respect and recognition of colleagues, patients, and families when faced with difficult clinical decisions.

The results of the univariate analysis revealed that nurses' moral courage scores varied by gender, age, work

department, years of working, professional title, whether or not had received medical ethics training, and marital status. In this study, the moral courage of male nurses was lower than that of female nurses, and one possible explanation is that under the influence of traditional concepts in Chinese society, male nurses not only suffered from prejudice and discrimination from society, patients, and family members but also faced hostility from within the healthcare workforce [41], which greatly affected their enthusiasm for nursing, and thus male nurses mostly adopted the negative strategy of avoidance in the face of the reality of ethical dilemmas. Older nurses, who have more years of working, and have higher professional titles, show more morally courageous behaviors, which is largely similar to the findings of existing studies [12, 38], and this may be because younger nurses usually undertake routine and general patient care, lack experience of moral courageous actions, and become overwhelmed when encountering situations triggering ethical distress; similarly, nurses with higher job titles tend to undertake more specialized and skilled care of acute and critical patients, and as their work experience grows, individuals become more aware of special situations and able to recognize behaviors and are more comfortable in dealing with ethical dilemmas or conflicts. ICU is the setting where moral dilemmas and challenges most often arise, and previous studies have shown that ICU nurses have higher levels of moral courage [42, 43]. However, in this study, nurses working in ICUs showed lower levels of moral courage, the reason for this may be analyzed to be related to the different time points of data collection, as the survey sample of this study was collected after the opening of the new coronary pneumonia epidemic, whereas the samples of the other studies originated from the period of the new coronary pneumonia pandemic, during which time, admissions to the ICUs in all hospitals increased dramatically, and the nurses would have been faced with ethical dilemma situations more frequently. This is consistent with Numminen's [44] conceptual analyses of moral courage which suggest that "experience" is a prerequisite for the development of moral courage. In addition, the moral courage of nurses who had received medical ethics training was higher than those who had not, which is consistent with a study by DeSimone [45] regarding the positive effect of ethical knowledge base, ethics training, and education on the level of moral courage. Finally, the results of this study also showed that marital status may also be a factor influencing moral courage among

nurses, and unmarried nurses had lower moral courage scores than married, the reason for this may be that unmarried nurses have a lower level of social support, receive less emotional support, and are more isolated, which may affect their courage to speak up and act courageously in situations filled with challenging ethical dilemmas. These indicate that managers should pay more attention to the work status of junior nurses, nurses working in ICUs, and single nurses; support them to be able to bravely express their views when they encounter ethical dilemmas at work; and respect their ethical decision-making while ensuring that patients' rights and interests are not compromised. As a component of nurses' moral competence, moral courage is a personal characteristic that can be learned and developed, and hospital administrators should include training courses on moral courage in their daily training to encourage nurses to play the role of moral courage in practice and bravely carry out their obligations to protect patients. Some countries have included moral courage training courses in their teaching curricula with more positive results, and their training methods are worth exploring and practicing.

Our study shows that ethical leadership has a positive impact on nurses' moral courage, consistent with several existing studies suggesting a significant positive relationship between ethical leadership and moral courage [46, 47], nurses perceive a higher level of ethical leadership from nurse managers, and more moral courage they are inspired to have Traditional Chinese culture often emphasizes the differences between the upper and lower levels and the order of respect and inferiority, with leaders often occupying a more crucial dominant position in an organization and having a more prominent influence on their subordinates. When nurse leaders demonstrate ethical leadership behaviors that are more focused on the work process, the interests of nurses, and doing the right thing, they are more effective in inspiring the formation of moral courage in nurses. In addition, the present result supports the previous finding of a positive correlation between ethical leadership and psychological empowerment [27]. Psychological empowerment is a motivational state that is achieved through a combination of job meaning, autonomy, self-efficacy, and perceived impact of work. It has a positive orientation towards employees' work so that they are interested and feel empowered to shape their work environment. Ethical leadership often takes into account the growth and developmental needs of each nurse, motivates nurses to perform core job duties, and puts them in a position where they can experience appropriate and meaningful work roles in their careers, thereby influencing their psychological empowerment and motivating them to be proactive rather than passive in their work. Finally, this study showed a positive relationship between psychological empowerment and moral courage. When nurses have high levels of psychological empowerment, they will be more likely to demonstrate higher levels of morally courageous behavior. Malak et al. found that nurses with high levels of psychological empowerment believe in their ability to do all things well at work, are less psychologically stressed in the work environment, and are more motivated to serve their patients [48]. Thus, it can be seen that having

a high level of psychological empowerment will motivate nurses to comply with the code of ethics and still choose to protect patient's rights and interests when their legitimate rights and interests are compromised, without fear of being threatened, fearful, or even losing their jobs.

The results of SEM showed that ethical leadership had a direct effect on nurses' moral courage (95% CI excluding 0, $p < 0.05$), and ethical leadership could also have an indirect effect on nurses' moral courage through psychological empowerment (95% CI excluding 0, $p < 0.05$), and that psychological empowerment partially mediated the relationship between ethical leadership and nurses' moral courage, which support Hypothesis 4 of the study. The results of this study show that ethical leadership directly and positively influences nurses' moral courage, with the direct effect accounting for 35.2% of the total effect. According to social learning theory, personal behaviors, especially more complex behaviors, can be acquired by individuals by observing and learning to imitate the behaviors of their role models; however, the type of behaviors accepted and the effectiveness of their implementation depend on the role of the role model. Previous research has shown that leader style is the most important situational factor influencing employees' moral courage [49]. As leaders and role models for nurses, ethical leaders respect nurses, handle all matters at work with fairness and integrity, and encourage nurses to speak up for patient rights when faced with situations that undermine patient rights and interests in nursing practice, which in turn leads to the conscious occurrence of moral courage among nurses. Therefore, nursing managers should strengthen their ethical leadership construction, set an example in their work, and play an exemplary role; for hospital organizations, they should establish a correct orientation for selecting and employing people, and pay attention to selecting and employing managers with moral leadership qualities.

Our study found that the influence of ethical leadership on nurses' moral courage can also be indirectly influenced by psychological empowerment, i.e., ethical leadership can promote nurses' psychological empowerment and then stimulate nurses' moral courage, and the size of the mediating effect of psychological empowerment between the two is 0.247, and the indirect effect accounts for 64.8% of the total effect, suggesting that psychological empowerment plays an important role between ethical leadership and nurses' moral courage. This suggests that moral leadership plays an important role in the relationship between ethical leadership and the moral courage of nurses. Ethical leadership makes nurses feel stronger psychological empowerment in their work so that they dare to do the right thing in favor of patients' rights and interests when they encounter situations that are contrary to patients' rights and interests in their practice. Therefore, to improve the moral courage of nurses, it is important to improve the level of ethical leadership of managers and the nurses' psychological empowerment. The results of this study support the relationships and mechanisms proposed in the social learning theory model, whereby a combination of personal cognition and the environment influences the behavior of the learning

individual. Ali Awad and Al-Anwer Ashour [50] also reached a similar conclusion, in whose research, ethical leadership affected moral courage through ethical climate as a mediating variable. Based on the above discussion, intervening in nurses' moral courage from the perspective of psychological empowerment may yield better results. It suggests that nursing managers should integrate ethical awareness and ethical behaviors into the daily work of clinical nurses to enhance the intrinsic motivation and sense of the meaning of nurses' work, which will, in turn, promote the formation of morally courageous behaviors.

8. Limitations

This study has some limitations to take into account. First, the study was only conducted in Sichuan Province, southwest China, with limited geographic areas and hospitals involved, therefore, the results obtained need to be validated more extensively in other regions or countries. Second, it may have resulted in reporting potential bias since we relied on self-report questionnaires, there may be a self-glorification of the investigator. Furthermore, the study used convenience sampling, and despite an adequate sample size, the number of male nurses in our study was too small, which may have contributed to selection bias. Finally, the cross-sectional design demonstrates that a causal relationship is not possible, and future research could try to conduct qualitative and longitudinal studies.

9. Conclusions

This study explored the correlation between nurses' perceived ethical leadership, psychological empowerment, and moral courage. As expected, ethical leadership and psychological empowerment influenced moral courage among nurses, and psychological empowerment partially mediated their relationship. Nursing managers must adequately recognize the link between these variables and adopt an ethical leadership approach to increase nurses' psychological empowerment and improve their moral courage.

10. Implications for Nursing Management

The results of this study show that the moral courage of nurses is moderately high, and ethical leadership and psychological empowerment positively influence it. We suggest hospital administrators pay attention to developing moral courage in nurses by emphasizing that ethics is integral to nursing practice. For example, training on moral courage as part of the nursing ethics curriculum and providing nurses with knowledge of moral courage. Similarly, nursing management should make a prerequisite to understand the meaning of ethical leadership and to identify with the sense of ethical leadership, take the initiative to learn the relevant theoretical knowledge of leadership and ethics, enhance the knowledge and awareness of the ethical leadership style, and create a good working environment and ethical atmosphere so that nurses can obtain psychological empowerment, thus stimulating the potential for the formation of moral courage in nurses.

Aims. To develop an evidence-based practice (EBP) facilitating strategy informed by the Integrated Promoting Action on Research Implementation in Health Services (i-PARIHS) framework and evaluates the strategy's effectiveness on promoting EBP. **Background.** Nurses are increasingly expected to use research evidence in practice to improve patients' outcomes, but the application of such evidence is still unsatisfactory. The facilitation of EBP in nursing needs the organization and the individual levels. **Methods.** Based on an analysis of EBP-promoting strategies and expert consultation, the core team of the nursing department developed an EBP group-based and project-oriented strategy under the guidance of the i-PARIHS framework. The strategy was implemented for six years and evaluated by a longitudinal design. The validated Chinese version of the self-reported Evidence Based Practice Questionnaire (EBPQ) was used to assess the attitudes, knowledge, and practice of the nurses. **Results.** The mean score of the total EBPQ was 4.46 (SD = 0.92) after one year of the EBP strategy, and the scores for knowledge, attitudes, and practice of EBP members were higher than those of general nurses ($p < 0.05$). After four years, EBP members' scores continued to increase. EBP groups conducted 51 EBP projects in the areas of emergency nursing, surgical and medical nursing, critical care, and so forth. Of these, 33 projects improved nursing practice by changing nursing procedures, upgrading nursing tools, and developing nursing standards, resulting in improved patient outcomes. **Conclusion.** The EBP group-based and project-oriented strategy can promote EBP. The composition of the EBP group, the annual audit of EBP projects, and the roles of internal and external facilitators were key components of this EBP-facilitating strategy. **Implications for Nursing Management.** The strategy is an organizational-level EBP-facilitation approach which can improve nurses' academic preparation for EBP through ongoing training and sustained EBP behavior that involves annual projects.

1. Background

Evidence-based practice (EBP) involves integrating the current best evidence with clinical expertise, information on patient preferences, and available resources into the clinical decision-making process [1, 2], and it is critical to achieving optimal patient outcomes at the lowest possible cost [3]. As one of the important groups of practitioners in health care, nurses are increasingly expected to translate research evidence into practice to improve patients' outcomes [4–6]. Considerable research, resulting in the development of various theories/frameworks, policy, and funding as related

to EBP, has been conducted [7–10]. Recent reviews show that education programs, reminders, and the use of champions help to ensure that nurses are aware of and use research evidence in clinical practice [11–13]. Nevertheless, applying the best research evidence into practice remains challenging. Further, there is limited understanding regarding which facilitation approaches are the most effective in enhancing evidence-based practice in certain contexts. [14].

Due to the dynamics and variability of evidence, complexity of the clinical environment, and differences in the capabilities of nurses, the implementation of EBP is still

unsatisfactory, especially in low- and middle-income countries. Researchers have identified barriers to implementing evidence-based practice [15, 16] that include individuals' lacking the necessary knowledge and skills as well as organizations' not having enough funding or institutional support for EBP, among others [15–18]. Thus, it is critical to find ways to enhance the integration of research evidence into nursing practice.

In China, researchers have conducted surveys on the attitudes, knowledge, and skills of registered nurses (RNs) as related to EBP [19, 20]. Most nurses had positive attitudes toward EBP but lacked sufficient knowledge and skills for implementation [20, 21]. Despite the considerable effort taken to implement EBP in China and an increase in the number of EBP projects since 2013 [22, 23], there is an urgent need for EBP resources, increased support from clinical management, and collaboration between academic and clinical institutions. Further, unlike the case of physicians who have greater EBP knowledge [24] and hold more authority in medical domains, the focus of EBP implementation in nursing needs to be at the group or organization and individual levels [25]. Thus, our research aims to develop a strategy that includes the organizational aspect of facilitating EBP in a general hospital.

Facilitating EBP among nurses in a tertiary general hospital requires supportive evidence and a theoretical framework. The Promoting Action on Research Implementation in Health Services (PARIHS) framework is a multidimensional approach that posits that the successful implementation of evidence into practice is influenced by three key factors: the quality and type of evidence, characteristics of the setting or context, and the manner in which the evidence is introduced into or facilitates practice [26, 27]. PARIHS has been used extensively in a diverse range of settings and with various uses, including planning and delivering an intervention, data analysis, and the evaluation of study findings [26]. Nevertheless, the PARIHS framework has been criticized for lack of clarity in regard to its elements/subelements, definitions of key outcomes, and the relationships among elements/subelements [28]. The Integrated Promoting Action on Research Implementation in Health Services (i-PARIHS) framework was developed and refined by the PARIHS group and is now used in evidence-based projects globally [27]. The i-PARIHS framework addresses concerns about the conceptualization of as well as relationships and dynamics among the main framework elements, namely facilitation, innovation, recipients, and context [27].

We hypothesized that the i-PARIHS framework also is suitable to guide a program for facilitating EBP in our hospital. This hypothesis is based on the framework's comprehensive approach, which considers the complex interplay of evidence, context, and facilitation, an approach that is particularly relevant, given the unique challenges that nurses face. Based on the analysis of available knowledge translation strategies and characteristics of the hospital and nursing environment, we set up and implemented a group-based and project-oriented EBP strategy that has been sustained for six years. This study presents the development

of this strategy and evaluates its effectiveness to shed light on the strategies and conditions that contribute to its success and limitations and to provide insight that can inform future efforts to promote EBP among nurses in similar settings.

2. Methods

2.1. Study Design. This study developed an EBP group-based and project-oriented strategy informed by the i-PARIHS framework and used a longitudinal design to observe the strategy's effectiveness. The framework was used to guide the development of the EBP-facilitating strategy at the hospital level. The strategy was practiced in a general hospital under the supervision of the nursing department for six years. The practice of the strategy from 2016 to 2019 was considered as the implementation phase. Also, year 2020–2021 was the sustained phase.

2.2. Setting and Participants. The study was conducted in a tertiary general hospital located in Hangzhou, Zhejiang Province, China. Because the hospital has a number of specialties, the Nursing Department was able to select six specialties which had more advantages and resources, and to set up EBP groups in 2016: Emergency and Intensive Care, General Surgery, Orthopedics, Neurology and Psychiatry, Gastroenterology and Respiratory Medicine, and Nursing Management. Nurses in these related departments who met the criteria could apply to participate in the study. Recruitment criteria included being committed to EBP, having certain skills related to EBP, priority will be given to candidates holding a master's degree or being a head nurse. A total of 34 nurses were recruited into six EBP groups based on these recruitment criteria. The groups were managed by the core team of the nursing department on an annual basis, and the number of groups was increased to 11, with 96 nurses, in 2021. The specialties of Neurosurgery, Intravenous Therapy, Operating Room, and Enteral Nutrition were added, and Emergency and Intensive Care were separated into two groups. The EBP group formation process and membership renewal are described in detail in the section of the EBP-facilitating strategy. Table 1 shows the number of groups and nurses in each year.

2.3. EBP-Facilitating Strategy. A core team of the nursing department was set up to develop the EBP-facilitating strategy. The team included the director of nursing; vice director of nursing, who was in charge of nursing research and education; and three senior nurses who had received EBP training outside the hospital. The project was "Facilitating evidence-based nursing from the hospital level," and the goal was to promote EBP for the nurses. Meetings of experts in the core team were conducted. Based on the analysis of EBP-promotion strategies and characteristics of the hospital and nursing environment, the team developed an EBP group-based and project-oriented strategy under the guidance of the i-PARIHS framework. In the framework, successful implementation involves facilitation of the innovation in coordination with the recipients in their local,

TABLE 1: Number of groups and nurses in each year.

Year	Groups (<i>n</i>)	Nurses (<i>n</i>)	Head nurse/supervisor (<i>n</i> , %)	Master's degree (<i>n</i> , %)
2016	6	34	13 (38.24)	13 (38.24)
2017	8	49	20 (40.82)	16 (32.65)
2018	8	54	17 (31.48)	26 (48.15)
2019	8	56	20 (35.71)	29 (51.79)
2020	10	83	28 (33.73)	35 (42.17)
2021	11	96	28 (29.17)	46 (47.92)

organizational, and healthcare system contexts [27]. The core elements of the framework are facilitation, innovation, recipients, and context [27]. The identification and integration of the core elements of our strategies are presented in Table 2.

The recipients of this project were the nurses who formed several EBP groups. Initially, six EBP groups, each with a specialty, were set up after an applicant assessment process. Each group elected one person as the leader to run each EBP project on an annual basis. Facilitation is the dynamic component that is involved in evaluating, harmonizing, and merging the other three elements [27]. The facilitation process is shown in Figure 1.

As the internal facilitators, the core team of the nursing department knows the level of EBP skills among the nurses. They invited experts from the Fudan University JBI Evidence-based Nursing Cooperation Center as external facilitators, which provided a structured training program and oversight of the conduct of each EBP project. The first training program involved education and assignments that involved choosing and identifying an EBP problem, reporting the retrieval results, evaluating the quality of the included literature, conducting a meta-analysis, and developing a plan of evidence application project. The training had 32 hours and lasted for two months, and the projects were evaluated at the end of the year. During the second year, the EBP groups continued to conduct new EBP projects.

The core team influenced and coordinated the process, including making decisions to increase or adjust the members and number of groups according to the qualifications of the members and groups. The coordinator updated the group membership annually and arranged for continuous training for new members by an external EBP training program or internal training by experienced members. The training for the new members had four aspects, including identification of an EBP problem, database retrieval, evaluation of the quality of the literature, and the process of evidence application. The training usually was conducted in the first quarter of the year. In addition to the training, the core team organized at least three meetings to assess the process of the EBP projects each year, including the choice of EBP projects, and engaged in ongoing assessment and with the conclusion of the projects. The external facilitator attended meetings more frequently during the first several years until the internal facilitators were sufficiently experienced and groups had gained more experience in implementation of evidence. From 2020, the practice of the strategy entered the sustained phase, the

number of EBP group members increased considerably, as the core team planned to extend the activities of EBP throughout the hospital. Then, a second structured training program was held, for which the main focus of the training was the application of evidence.

2.4. Data Collection. The validated Chinese version of the self-report Evidence-Based Practice Questionnaire (EBPQ) was used to assess the attitudes, knowledge, and practice of the group members of the EBP projects and general nurses in the same hospital.

The EBPQ was developed by Upton and Upton [29] and was translated into Chinese by Yang and Tang in 2009 [20]. The Chinese version of the EBPQ consists of 24 items allocated to three subscales: knowledge/skills (14 items), attitudes (4 items), and practice (6 items). Each item is rated from 1 to 7, with a higher score as indicating more knowledge, a more positive attitude, or better utilization in regard to EBP. Cronbach's alpha of the Chinese version was 0.94, and the subscales' values were 0.79 to 0.94 [20]. The response to each item was deemed positive if the score exceeded 4. For data analysis, we applied the means of the scores of each subscale and the total EBPQ score. The Chinese version of EBPQ was obtained from the authors for use.

The first survey was administered to EBP group members through a manual questionnaire during February 2017 (T1) after the EBP-facilitating strategy had been applied for one year. The same questionnaire was also administered to general nurses who attended in-service training classes within the hospital. To ensure timely and efficient data collection, we employed convenience sampling to select four classes that were held for different levels of nurses. This method allowed us to readily access a pool of nurses with varying levels of expertise who were available and willing to participate in the study. The second survey was electronic, administered to EBP group members during December 2019 (T2), when the EBP-facilitating strategy had been applied for four years.

During the ongoing assessment and for the concluding report of the EBP projects each year, the core team of the nursing department assessed the results and used a self-designed form to create a record of the project. The form included the information on the project, whether the evidence was applied to clinical practice, and the reasons for the lack of success, if relevant, of the application. The information included the title of the project, group name, setting and population, and main clinical and academic

TABLE 2: Identification of core elements in the EBP-facilitating strategy.

Core element	Strategy
Innovation	Enhance the evidence-based practice skills of nurses Promote the application of research evidence to inform the innovation
Recipients	EBP groups formation process: (a) The core team developed the recruitment criteria Recruitment criteria: committed to EBP; have skills related to EBP; encourage master's degree and head nurses to participate (b) Nurses submitted the application to nursing department (c) The core team assessed the applicants and set up EBP groups. Principles: each group had nurses from the same or related specialties and comprised nurses in a leadership position (head nurse/supervisor/vice director) and who had a master's degree
Context	Local level Same or related specialties had a similar setting and environment, which ensured the same interest in choosing EBP questions and enabled the implementation of research evidence Organization level Hospital and nursing department supported and provided training, multidiscipline collaboration, and necessary facilities External healthcare system level The priority was to narrow the gap between evidence and practice and improve patients' outcomes; this was hampered, however, by a lack of EBP skills
Facilitation	Facilitators Internal facilitator: the core team of nursing department; one member was assigned as the coordinator of this project External facilitator: three members of the Fudan University JBI Evidence-based Nursing Cooperation Center Facilitation strategies The core team organized a two-month intermittent training of EBP guided by a well-educated EBP team Each EBP group was required to conduct one EBP project per year. Regular meetings were held for audits of the projects The coordinator tracked the process of each EBP project and provided regular feedback The coordinator reviewed and updated the members of EBP groups annually An external facilitator navigated the implementation of evidence in projects

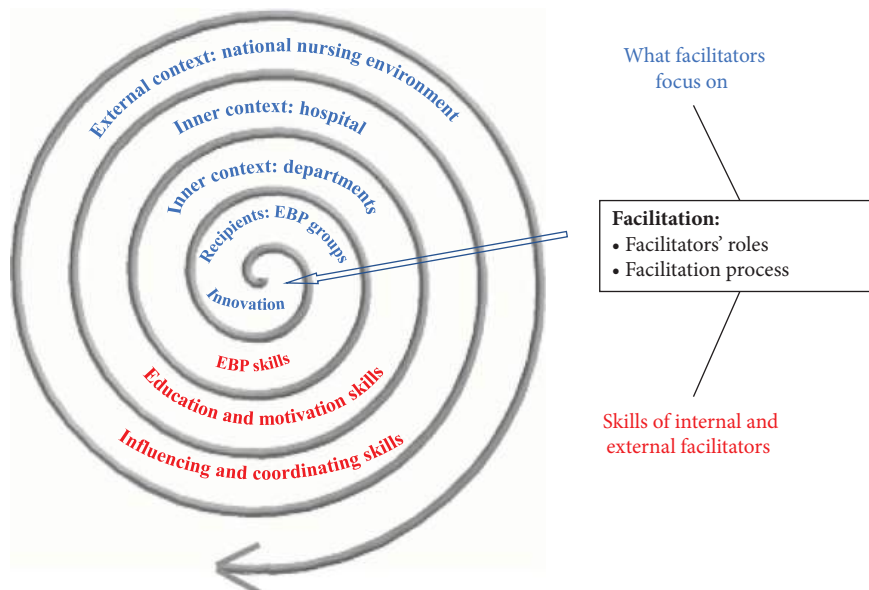

FIGURE 1: Facilitation process of the EBP-facilitating strategy.

outcomes (e.g., whether a paper was published, whether expert consensus was achieved). The main reasons for a lack of success included insufficiency of the evidence, small gap between current practice and evidence, stakeholder conflicts, and insufficient leadership during evidence implementation. Two members of the core team determined the reasons after discussion with the leader of each EBP group.

2.5. Data Analysis. The scores for the knowledge/skills, attitudes, and practice subscales were continuous variables, which were presented as means and standard deviations (SD). The differences between the two groups and the two time points were analyzed using an unpaired Student's *t*-test. A two-tailed *p* value of <0.05 was considered statistically significant. The analyses were performed using SPSS 24.0.

3. Results

The mean scores of the total EBPQ were 4.46 (SD = 0.92) after the training and one year of the EBP-facilitated program. The scores for knowledge, attitudes, and practice of the EBP group members were higher than those of general nurses (all *ps* < 0.05). Among EBP members, the scores for knowledge, attitudes, and practice increased after four years of the program (T2), and the differences were significant (all *ps* < 0.05). Table 3 presents these results.

EBP groups conducted 51 EBP projects that covered emergency nursing, surgical and medical nursing, critical care, nursing management, and so forth. Among the projects, 33 were found to improve nursing practice, as seen in changes of nursing procedures, upgrading of tools, development of nursing standards, and improvement in patient outcomes. For example, the emergency group formulated an EBP for rewarming for patients with traumatic hypothermia, including developing the warming-starting standards, clinical warming methods, and monitoring frequency. A total of 41 patients with traumatic hypothermia participated in the nursing program. The mean temperature of patients was (36.31 ± 1.12) °C when leaving emergency room, and the increase in patients' temperature was (0.82 ± 0.56) °C, which was higher than that before the EBP program (*p* < 0.05). In addition, the percentage of patients with chills was 2.44%, which is significantly lower (*p* < 0.001). Finally, 18 projects were not successful. The main reasons included stakeholder conflicts (6 projects), insufficient leadership during evidence implementation (5 projects), a small gap between current practice and evidence (5 projects), and a lack of evidence (2 projects).

4. Discussion

In our study, we employed the i-PARIHS framework to guide an organizational-level EBP-facilitation approach that used an EBP group-based and project-oriented strategy to improve evidence-based practice among nurses in a tertiary general hospital. The results of the first survey indicated that the EBP group members generally viewed EBP positively and had higher knowledge/skills, and practice levels than did general nurses. The baseline of the two groups differed, but

the results indicated that the EBP group members had higher skills and a better attitude. The use of intermittent training of EBP, similar to a 30-hour EBP training intervention, was effective in improving the knowledge, attitude, practice, and competency of EBP among nurse educators [30]. The results of the second survey showed that the knowledge, attitudes, and practice of the EBP group members had an upward trend. A systematic review showed that the most frequent types of knowledge transition interventions implemented were educational and interactive, which were more effective than was didactic (Forsetlund et al., 2009; [12]). In our study, the interaction within the group during the implementation of the project as well as between the teachers (external facilitators) and students (EBP group members) explained the large effect in regard to improving knowledge, attitudes, and the practice level of nurses.

The i-PARIHS framework offers a structured approach for the implementation of EBP, allowing researchers to systematically consider all key factors that influence implementation, including evidence, context, and facilitation. In our EBP-facilitating strategy, the composition of the EBP group, roles of internal and external facilitators, and annual audit of EBP projects were the key components.

Lack of academic preparation is one of the barriers to EBP; appropriate composition of and training courses for groups, however, can address this barrier. Nurses with a master's degree had a better understanding of EBP and the associated skills and were able to help retrieve and synthesize the evidence that is the basis of the project. This is the reason that we utilized a high percentage of nurses with a master's degree in the groups. The leader of the group is crucial during the project; thus, a head nurse or supervisor was appointed as the leader because such an individual possesses the type of leadership that enables successful implementation. A nurse manager (head nurse or supervisor) has a particularly influential role in the implementation of EBP in terms of providing a supportive culture and environment [31–33]. The lack of sufficient leadership during evidence implementation can lead to failure, which is what occurred in five projects.

The role of facilitation in the process of implementation is a key factor in enabling the successful implementation of our EBP-facilitating strategy. The core team of the nursing department worked as internal facilitators, making the process smoother by motivating the EBP groups and continuously monitoring the process of the EBP projects. External facilitators were outside experts who brought specialized knowledge and a fresh perspective. As internal resources were insufficient for EBP, these external facilitators trained internal ones and provided ongoing systematic training and guidance during each project.

The ongoing projects, conducted each year, motivated EBP group members to use research evidence and change nursing practice. As noted in the second survey, a prominent upward trend was observed in the knowledge, attitudes, and practices of EBP group members. Despite 18 projects that failed to effectuate a change in practice, members of the EBP group acquired valuable experience, contributing to their growth in the domain of evidence-based practice. Of the projects undertaken, 33 demonstrated significant

TABLE 3: Comparison of nurses' EBP knowledge/skills, attitudes, and practice (mean \pm SD).

Group	<i>n</i>	Knowledge/skills	Attitudes	Practice	Total
EBP members	40	4.31 \pm 0.99	5.38 \pm 0.90	4.20 \pm 1.014	4.46 \pm 0.92
General nurses	152	3.85 \pm 0.75	4.64 \pm 1.00	3.84 \pm 0.91	4.02 \pm 0.69
<i>t</i> value		2.745	4.185	2.115	3.769
<i>p</i> value		0.008	<0.001	0.036	<0.001
EBP members (T1)	40	4.31 \pm 0.99	5.38 \pm 0.90	4.20 \pm 1.14	4.46 \pm 0.92
EBP members (T2)	48	4.74 \pm 0.97	5.80 \pm 0.81	4.96 \pm 1.21	4.97 \pm 0.89
<i>t</i> value		-2.072	-2.299	-3.010	-2.649
<i>p</i> value		0.041	0.024	0.003	0.010

improvements in nursing practice. These enhancements included modifications to nursing procedures, advancement of tools, development of nursing standards, and enhancement of patient outcomes. This is in keeping with the primary objective of this study, as evidenced by these EBP projects, which was to augment the efficacy of our EBP-facilitation strategy.

4.1. Limitations. The main limitation of this study was that the design was a one-arm study, with the lack of a comparison study to evaluate the effect of this group-based and project-oriented EBP strategy. Nevertheless, we observed the effect of the strategy from a longitudinal perspective (over six years) and found the strategy suitable for the culture and characteristics of our hospital. Moreover, the strategy can be applied to similar settings. Finally, had we assessed the knowledge, attitudes, and practice of the nurses each year, our findings would have been more rigorous.

5. Conclusion

Earlier research typically focused on one targeted clinical problem or on changing nursing behavior, with limited focus on knowledge translation interventions or strategy from an organizational perspective. We developed a group-based and project-oriented EBP strategy, under the guidance of the i-PARIHS framework that can promote the knowledge and attitudes of nurses and increase their level of practice, thus improving patients' outcomes. The composition of the EBP group, annual audits of EBP projects, and the roles of internal and external facilitators were key components of this EBP-facilitating program.

6. Implications for Nursing Managers

Enhancing EBP among nurses in general hospitals is critical to nursing quality, but there are still shortfalls in practice, especially in under-resourced countries. The i-PARIHS framework provides a theoretical framework for the development of an organizational-level EBP-facilitation approach based on the context of the organization. This enriches the application of the i-PARIHS framework. An EBP group-based and project-oriented strategy can improve certain nurses' academic preparation for EBP through ongoing training and sustained EBP behavior that involves annual projects. Nursing research should continue to analyze the results of projects and the characteristics of EBP behavior to promote EBP.

Background and Objectives. The scarce empirical and scientific information concerning evidence-informed management reports various benefits for nurse managers, including reduced staff turnover, enhanced working environments, and improved patient outcomes and policy implementation. This review summarizes best available evidence on facilitating utilization of evidence-informed management practices by nurse managers in healthcare facilities. The review could assist in a comprehensive overview of determinants that could assist nurse managers' successful utilization of evidence-informed management. **Methods.** An integrative review of the literature was conducted, including peer-reviewed articles published between 2010 and 2022. The databases used were BioMed Central, CINAHL Complete, MEDLINE Complete, PubMed (via EBSCOhost), the Complimentary Index (Taylor and Francis, Elsevier, Wiley, and Springer), Sabinet, ScienceDirect, and Scopus, followed by a manual search using Google Scholar and a citation search. Johns Hopkins Nursing Evidence-based Practice Research and non-Research evidence tools were used for appraisal. Thematic analysis was used to synthesize the extracted data. **Results.** Based on thirteen determinants influencing nurse managers' utilization of evidence-informed management practices, three themes were identified from a total of thirteen relevant studies: (1) Nurse manager determinants in utilization of evidence-informed management (Microlevel); (2) Organizational determinants in utilization of evidence-informed management (Mesolevel); (3) External stakeholders and context determinants of utilization of evidence-informed management practices (Macrolevel). **Conclusion.** The themes were found to be interconnected and interdependent, facilitating the effective utilization of evidence-informed management by nurse managers at micro-, meso-, and macrolevels, but highlight the need for strengthening health systems and support. Future studies are required to provide a more comprehensive understanding of the determinants influencing nurse managers' utilization of evidence-informed management practices. **Implications for Nursing Management.** For nurse managers to optimally utilize evidence-informed management, executive management and policymakers require to provide resources and support such as continuous education, incentives, effective communication, funding structures, and ownership.

1. Introduction

Evidence-informed management, also known as evidence-based management, is a prominent approach in management and public health [1, 2]. It involves systematically utilizing the best available evidence to inform decision making, improve management practices in patient care and

nursing staff supervision, and achieve desirable organizational outcomes [3, 4]. "Evidence" encompasses data from research and non-research sources such as professional experience, feedback, and organizational information [5]. While "evidence-based management" tends to emphasize empirical evidence, "evidence-informed management" allows greater flexibility [6, 7]. Nurse managers, or middle

managers, play a crucial role in initiating, guiding, and sustaining evidence-informed management practices [8–10]. Utilizing evidence-informed management leads to reduced bias, improved efficiency, better patient outcomes, and strategic planning support [9–11]. Failure to employ evidence-informed management can result in ineffective decision making, increased costs, reduced productivity, and negative effects on patient satisfaction and organizational reputation [12].

Enhancing the utilization of evidence-informed management practices among nurse managers is crucial for optimizing clinical and organizational advantages [13]. Understanding the facilitators in complex healthcare environments is essential [1], yet its application in nurse management remains novel [10]. Additionally, there is a scarcity of empirical information on evidence-informed management in relation to nurse managers, posing limitations to understanding its uptake and utilization [14, 15], potentially leading to ineffective practices and policy implementation [12, 16].

Moreover, a gap exists in integrative literature reviews conducted in English on this topic, underscoring the need for a comprehensive review [17]. Such a review could offer insights into strategies and interventions for nurse managers to utilize evidence-informed management effectively, thereby enhancing management practices and improving nursing and patient outcomes.

Thus, the objective of this review is to summarize best available evidence on facilitating utilization of evidence-informed management by nurse managers in healthcare facilities. The review question guiding the review was: “What is the best evidence available regarding the facilitation of utilizing evidence-informed management by nurse managers in healthcare facilities?”

2. Materials and Methods

The review was conducted according to Whittemore and Knaff’s [18] stages for an integrative literature review. These stages include problem identification, searching, selecting, appraising, analysing and synthesizing, and presenting the data.

2.1. Search and Selection. With the assistance of the faculty librarian, a comprehensive search was conducted in November and December 2022. The following electronic databases were searched: BioMed Central, as well as CINAHL Complete, MEDLINE Complete, and PubMed (via EBS-COhost), the Complimentary Index (Taylor and Francis, Elsevier, Wiley, and Springer), Sabinet, ScienceDirect, and Scopus. Thereafter, a manual search for grey literature using Google Scholar and a citation search were completed. Databases were chosen in consultation with the faculty librarian, adhering to recommendations by Bramer et al. [19] for systematic review searches, ensuring retrieval of the most relevant scientific data. The following key search terms and/or phrases were used: “evidence-informed management” OR “evidence-based management” AND “Nurse Manager”

AND “utilization” OR “facilitation” AND “healthcare” OR “health facility.” Boolean operators assisted in further filtering the search. Key search terms were selected in consultation with the faculty librarian, in accordance with the PICO elements. The PICO elements included P (opulation): nurse manager, I (ntervention): evidence-informed management, C (ontext): health-care facility or context, and O (utcome): facilitating the utilization of the intervention (evidence-informed management), focussing on the “process” as an outcome as compared to improved management practices, nursing and patient outcomes. The Boolean operator “OR” and “AND” was used to combine these search terms with different syntaxes adapted to each database. Screening was done according to the following eligibility criteria as outlined in Figure 1.

After deduplication, titles and abstracts of all documents and full texts obtained were screened for relevance by D.R.C. and J.N. independently, using the inclusion and exclusion criteria. The researcher initially exported records to EndNote version X9 and thereafter recorded and tracked articles in Microsoft Excel. Each step used in the searching and selecting processes is illustrated in the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) flow diagram [20].

2.1.1. Critical Appraisal. After data reduction through the screening for relevance was finalized, critical appraisal using the Johns Hopkins Nursing Evidence-based Practice Research (for studies with Level I, II, and III evidence) and non-Research evidence appraisal tools (for literature with Level IV and V evidence) was undertaken by D.R.C. and J.N. independently. These tools are generic tools that present a structured approach to appraising studies that present evidence of different strengths and quality using a widely established quality grading scale of high, good, and low quality [21]. D.R.C. created an Excel spreadsheet and compiled a list of the articles for review, which was sent to the independent reviewer (J.N.) with an electronic fillable Word document of the applicable appraisal tools. For studies with Level I, II, and III evidence, the items related to the strength of the study design, study results, and study conclusions were answered by clicking “yes” or “no” and comments were made on the pertinent study findings and recommendations. For literature with Level IV and V evidence, similarly, the items pertaining to the type of evidence were completed by clicking “yes” or “no” and comments were made on the pertinent study findings and recommendations. In addition, literature was graded. Only literature that met the *High* (A quality evidence) and *Good* (B quality evidence) quality grading scale according to Dang and Dearholt [21] was included for data extraction. High quality evidence included studies with rigorous designs that produced consistent, generalizable results (quantitative) or those studied that included measures of trustworthiness (qualitative) or were scientific/expert opinion papers or literature reviews. Good quality evidence included studies with reasonable designs and results (quantitative), and those that included some measures of trustworthiness (qualitative) or were credible expertise

<p>Inclusion criteria:</p> <p>Literature:</p> <ul style="list-style-type: none"> • on all levels of evidence, including Level I – Randomised controlled studies (RCTs), meta-analysis of multiple RCTs; Level II – Quasi-experimental studies; Level III- Non-experimental studies; Level IV- Clinical guidelines; Level V- Opinion papers, allowing for a comprehensive summary of the literature, as recommended by Elsbach and van Knippenberg (2020). • published in the English language- the language the authors are proficient in and to avoid translation costs, • from January 2010 to December 2022 -to obtain the latest evidence, • relating to: <ul style="list-style-type: none"> o facilitating nurse managers’ (middle managers, who are senior registered nurses or midwives who assume strategic, functional and operational responsibility and accountability for a single or multiple patient care unit(s) or nursing work group (Case Management, Nursing Education and Research, Nursing Informatics) and provide clinical and managerial supervision for three or more staff (Cox, 2019))use of evidence-informed management in healthcare management and healthcare facilities, o factors contributing to nurse managers’ utilization of evidence-informed management, o interventions and on models of evidence-informed management. <p>Exclusion criteria:</p> <p>Literature:</p> <ul style="list-style-type: none"> • related to evidence-based practice in clinical management, • related to senior executive healthcare managers and • on evidence-informed management outside healthcare management and facilities.

papers (opinion papers and literature reviews) [21]. A briefing meeting was held between D.R.C., J.N., and W.T.H.B. to discuss the compiled list of articles for review, the appraisal tools, timelines for review completion, follow-up, and consensus meetings where critical appraisal outcomes (number of “yes” or “no” answers, and grading) were compared between reviewers and discussed—second and third meetings. W.T.H.B.’s role was to overview the process of critical appraisal and act as consultant when there were discrepancies between the two reviewers.

2.1.2. Data Synthesis. After the critical appraisal, the data from included articles were manually extracted by D.R.C. using a self-developed data extraction tool (Excel spreadsheet), as suggested by Lubbe et al. [22]. The data extraction tool included the reference, aim and setting of the study and summary of the study findings, recommendations, and implication(s) for practice (see supplementary file (available here) for the data extraction table). D.R.C. and J.N.

independently utilized a content analysis approach to analyse the data. This approach included reading and re-reading the extracted summarized findings and recommendations as well as the implication(s) for practice from the spreadsheet, assigning codes using an additional column, which were grouped in terms of commonalities (e.g., the phrase “Belief in the evidence is important for evidence-informed management implementation” was grouped under the code “Nurse managers’ attitude and behaviour towards evidence-informed management”) [18, 22]. The final code book was derived through verification of both sets of grouped codes. Grouped codes were synthesized by re-categorization under broad headings, with the aim of deriving themes (three themes outlining the various determinants). For example, the grouped code “Nurse managers’ attitude and behaviour towards evidence-informed management” was categorized as one of the nurse manager determinants in utilization of evidence-informed management—Theme One. Any disagreements were resolved through consensus discussions between the authors.

2.2. Data Presentation. The developed themes were presented in a sequential order, starting with those that had the most supporting evidence and concluding with themes that had comparatively less supportive evidence. The level or strength of the evidence was also described for each theme. Data were reported as a narrative, supported by tables and figures.

2.3. Rigor of the Review. Overall quality and rigor of the review process were maintained using the structured process and steps articulated by Whitemore and Knafl [18]. Several steps were taken to mitigate bias and ensure rigor during the review process. In terms of the search, this was conducted by a team of researchers, including an experienced librarian; a thorough search strategy was used with carefully selected keywords and databases and the search was recorded using the PRISMA, as recommended by Batten and Brackett [23]. For the screening and data extraction processes, two reviewers independently screened the literature for inclusion in the study. Furthermore, the use of credible critical appraisal tools, using an independent reviewer, and use of a data extraction form in the form of a spreadsheet enhanced rigor [24, 25]. Finally, the transparent documentation of each step of the review process enhanced replicability of the process [26].

3. Results

3.1. Search and Selection Results. A total of two hundred and ninety-six ($n = 296$) articles were identified from searching the electronic databases. After deduplication and screening titles and abstracts, $n = 41$ articles were retained. The manual search and citation search yielded an additional three articles. A total of $n = 44$ full-text articles were screened for possible inclusion in the selection, leading to the exclusion of $n = 29$ articles and a further exclusion of two ($n = 2$) articles after critical appraisal. Thirteen articles met the inclusion criteria and were therefore included in the review (see Figure 2).

3.2. Quality of Evidence. Most studies ($n = 11$) were non-experimental research, including qualitative ($n = 6$), quantitative ($n = 4$), and mixed method ($n = 1$) designs, offering Level III evidence with *Good* (B) quality rating. The remaining two studies ($n = 2$) were non-research studies with Level V evidence and a quality rating of *Good* (B) [21]. The level of evidence and quality rating for all themes and related determinants were III(B), V(B).

3.3. Country. The studies were conducted in different countries, namely, Iran ($n = 4$), the United States of America ($n = 3$), Canada ($n = 2$), Australia ($n = 1$), Lebanon ($n = 1$), Pan-European ($n = 1$), and Scotland ($n = 1$).

3.4. Healthcare Context. Given the variety of countries in which the studies were conducted, the review of the healthcare contexts indicated diverse multicultural settings with varying socioeconomic and facility ownership policies. Contexts included rural, regional, and urban hospitals.

3.5. Determinants and Themes. Following the synthesis, thirteen ($n = 13$) determinants that were reported as facilitators and barriers to nurse managers' evidence-informed management utilization were identified. These determinants pointed to influences at different levels of the healthcare system—that is, the micro- (nurse manager level), meso- (organization level), and macro- (external) levels. The determinants were categorized under three main themes (see Table 1).

A comprehensive discussion of the themes and sub-themes is presented in the following section.

3.5.1. Theme One: Nurse Manager Determinants in Utilization of Evidence-Informed Management (Microlevel). At the individual nurse manager level within the healthcare system, there is a significant expectation and responsibility to effectively use evidence in management practice [13, 17]. Thirteen studies identified five determinants for nurse managers' utilization of evidence-informed management: appropriate training and competencies ($n = 13$), acting as knowledge brokers ($n = 12$), attitudes and behaviours ($n = 11$), experience and education level ($n = 10$), and availability of supportive tools ($n = 7$) (see Figure 3).

3.5.2. Determinant 1: Nurse Managers' Training, Knowledge, Skills, and Competencies. To enhance the utilization of evidence-informed management by nurse managers, ongoing education in skills such as evidence searching, appraisal, interpretation, and application is essential. This education should complement formal training through workshops and reading reports. Creating a supportive learning environment, fostered by peer coaching, mentoring, and exposure to evidence-utilization situations, further enhances nurse managers' capacity [1, 2, 13, 17, 27–32, 34].

3.5.3. Determinant 2: Nurse Manager as Knowledge Broker. Nurse managers, as middle managers, play a pivotal role as information hubs within healthcare settings, bridging the gap between various stakeholders by gathering, translating, and disseminating information. This knowledge brokering function facilitates change and enhances the integration of knowledge into practice. Achieving this role effectively necessitates flattened hierarchical structures, empowering nurse managers with the autonomy and authority to make informed decisions [34, 35].

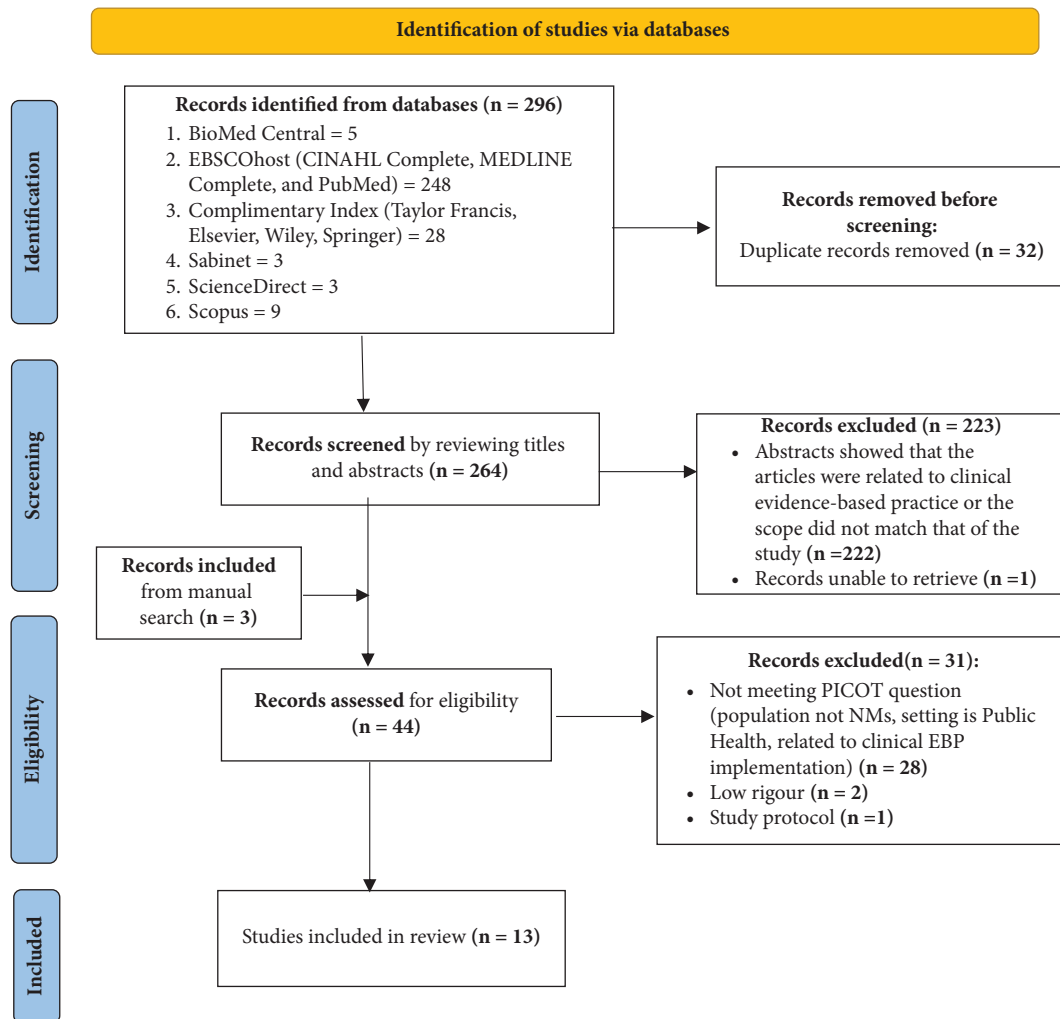

FIGURE 2: Flow diagram to illustrate data evaluation and reduction (adapted after [20]).

3.5.4. Determinant 3: Nurse Managers' Attitude and Behaviour towards Evidence-Informed Management. Nurse managers demonstrate positive attitudes and behaviours towards evidence-informed management by showing enthusiasm, motivation, and openness to innovation, along with utilizing performance data to inform decisions. Improving these attitudes and behaviours can be achieved through incentives, adequate resource provision, funding for innovation, and effective communication from senior management. Establishing policies, facilitating shared governance, and enhancing participation in decision making further support this culture [1, 2, 13, 17, 32–35].

3.5.5. Determinant 4: Nurse Manager Experience and Level of Education. Nurse managers with a Bachelor level of education were reported to be positively associated with promoting principles of quality [28]. However, Hasanpoor et al. [13, 17] found no correlation between level of education and experience of using evidence in management practice.

3.5.6. Determinant 5: Tools to Support Evidence-Informed Management Utilization. The synthesized data indicated five ($n=5$) tools the nurse manager can use to support evidence-informed management utilization (see Table 2).

3.5.7. Theme Two: Organizational Determinants in Utilization of Evidence-Informed Management (Mesolevel). The 13 included studies identified six organizational determinants (determinants 6–11) influencing evidence-informed management at a mesolevel: (1) robust organizational structures ($n=13$), (2) adequate and accessible resources ($n=13$), (3) supportive and learning culture ($n=12$), (4) information and technology ($n=12$), (5) positive leadership attitude and behaviours ($n=9$), and (6) ownership and funding structures ($n=4$) (Figure 4).

3.5.8. Determinant 6: Robust Organizational Structures. Organizational contexts necessitate the establishment of infrastructure encompassing systems, processes, and

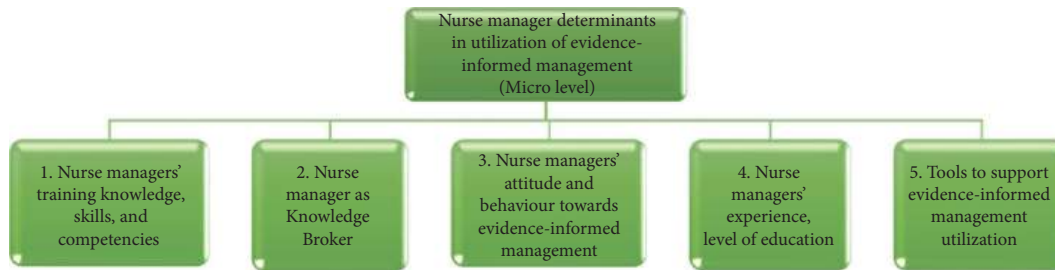

FIGURE 3: Nurse manager determinants (theme one).

structures to carry out the organization's mission in an evidence-informed manner [2, 32]. Robust organizational structures, characterized by a flattened hierarchy and open information flow, facilitate evidence-informed management. These structures, including networking structures for communication and collaboration within and external to the organization, enhance nurse managers' exposure to diverse information sources. They also facilitate engagement in peer-to-peer dialogue with university colleagues, thus strengthening knowledge brokering [13, 17, 31, 33].

3.5.9. Determinant 7: Adequate and Accessible Resources. Evidence-informed management necessitates investment in resources, including research teams, data analysts, and dedicated planning time. Supportive teams and adequate human resources, such as associate nurse managers or clerical support, are crucial to alleviate non-managerial tasks, enabling nurse managers to focus on evidence-informed management [13, 17, 27, 29, 30, 32, 33].

3.5.10. Determinant 8: A Supportive and Learning Culture. A supportive learning culture, essential for evidence-informed management, prioritizes staff development and infrastructure building [2]. This culture necessitates transparent communication on organizational priorities, staff participation, compensation systems, and feedback mechanisms. Accessible education and training programs on performance data usage, along with quality improvement tools, are vital for planning and knowledge translation [13, 17, 31, 32].

3.5.11. Determinant 9: Information and Technology. Organizations can support nurse managers' performance measurement through various resources, such as dashboards and wearable communication devices, aiming to improve efficiency, quality, and patient safety, thus promoting evidence-informed management [12, 13, 17, 30, 32]. Training nurse managers to utilize advanced data interpretation skills, including control and run charts, enhances their ability to utilize available information and technology effectively [12, 13, 17, 32].

3.5.12. Determinant 10: Positive Leadership Attitude and Behaviours. Leaders should embrace suggestions from nurse managers and model evidence-based behaviours, coaching them to do the same and shifting from a crisis management culture [2, 33].

3.5.13. Determinant 11: Ownership and Funding Structures. Ownership of an organization, whether government or private, significantly influences operations at the mesolevel, including the adoption of evidence-informed management. Private for-profit institutions often exhibit greater motivation for evidence use due to financial targets, whereas public institutions may lack such incentives [13, 32]. In low- to middle-income countries, limited resources, inadequate innovation, and a lack of incentivized programs hinder evidence-informed management. These challenges lead to reduced health expenditure, hampered networking, and limited communication and collaboration, particularly in rural areas [27].

3.5.14. Theme Three: The External Stakeholders and Context Determinants of Evidence-Informed Management Utilization (Macrolevel). At the macrolevel, two determinants (determinants 12 and 13) influencing evidence-informed management utilization were identified: (1) external stakeholders ($n=11$) and (2) context (socioeconomic, political, and ethical) ($n=8$) (see Figure 5).

3.5.15. Determinant 12: External Stakeholders. External stakeholders impacting nurse managers' use of evidence-informed management include regulatory bodies mandating performance data submission and setting performance targets [32]. Nurse managers are tasked with measuring this information and achieving the set targets.

3.5.16. Determinant 13: Socioeconomic, Political, and Ethical Context. Strong policies and discourses from the macrolevel external environment, particularly in socioeconomic and political domains, permeate organizational infrastructure at the mesolevel, significantly impacting individual nurse managers' utilization of evidence-informed management at

the microlevel. This influence extends through national politics, policy, and socioeconomic reform. Furthermore, ethical influences from government and agency regulations shape access to care and resource allocation through policies and processes [27].

4. Discussion

This review aimed to provide a comprehensive synthesis of the most reliable and up-to-date evidence regarding the facilitation of evidence-informed management utilization by nurse managers within healthcare facilities. Through an exhaustive analysis, a total of 13 determinants were identified which significantly influence the utilization of evidence-informed management by nurse managers. These determinants were further categorized into three overarching themes related to the utilization of evidence-informed management: (1) Nurse manager determinants at the microlevel (five determinants); (2) Organizational determinants (six determinants); and (3) External stakeholders and the broader context at the macrolevel (two determinants). It is important to note that despite operating at the microlevel within the organization, nurse managers are influenced by factors at the meso- and macrolevels, emphasizing the significance of considering determinants at all three levels to foster effective utilization of evidence-informed management. Hence, nurse managers should consider the influences from multiple levels to ensure successful utilization of evidence-informed management [37].

At microlevel, the development of nurse managers' knowledge, skills, and competencies in terms of accessing, appraising, and applying evidence in their decision-making processes is essential for effective use of evidence-informed

management. This notion is consistent with recommendations made in other studies [38, 39]. Strengthening nurse managers' knowledge, skills, and competencies in evidence-informed management is particularly critical, as a lack of competencies has been reported a common barrier to establishing a culture that supports evidence-informed practices [39, 40]. To enhance nurse managers' competencies, various strategies should be employed and supported by the executive management of a health organization. These include formal education through structured educational programs and ongoing professional development through web-based platforms and online educational resources, all of which should be aimed at enhancing nurse managers' competence and skills in utilizing evidence-informed management in decision-making processes, for example, through training in critical appraisal [39, 41]. Furthermore, access to reliable sources of evidence, such as databases, journals, and research articles, equips nurse managers with the necessary information to make informed decisions while assisting them to gain autonomy to be Knowledge Brokers. In addition, the education pertaining to evidence-based management, whether provided in a formal or informal setting, should also include the utilization of supportive tools identified in our review—including frameworks, models, and decision-making tools.

However, it is important to note that competence in utilizing evidence-informed management may not be sufficient on its own but requires a change in positive attitudes and behaviours. Our review revealed that nurse managers' positive attitudes and behaviours towards evidence-informed management are crucial determinants of utilization, as they encourage them to question prevailing practices. We identified in existing literature several strategies in our review that can enhance nurse managers' attitudes and

behaviours towards evidence-informed management, including incentives such as incorporating evidence-informed management competencies into performance evaluation criteria, providing access to adequate human and monetary resources, effective communication that fosters shared governance among nurse managers, and participation in decision-making processes [42]. However, it should be noted that these strategies primarily address extrinsic factors influencing behaviour, while there is limited understanding of the intrinsic factors that drive behaviour towards evidence-informed management utilization, necessitating further exploration in this area. Furthermore, although most nurse manager determinants are largely influenceable by the nurse manager, the findings of our review indicate that the cultivation of an effective Knowledge Broker role (determinant 2) necessitates the presence of flattened hierarchies within organizational structures. Such hierarchical flattening serves as a facilitator for the dissemination and utilization of pertinent evidence. Moreover, this process is not solely contingent upon the influence exerted by nurse managers; rather, it is contingent upon the establishment of a corporate culture characterized by flexibility, egalitarianism, and transparent communication in its approach to evidence-informed management and its paradigms [43].

At mesolevel, our review highlights the significance of organizational determinants in facilitating nurse managers' utilization of evidence-informed management. Organizational determinants are particularly important since they play a crucial role in organizational change and influence evidence-based organizational practices [39, 44]. We identified several key elements of the organizational context that contribute to this utilization, including robust organizational structures, ownership and funding mechanisms, and the availability of adequate and accessible resources, such as information and technology. Furthermore, a supportive and learning culture characterized by positive leadership attitudes and behaviours was found to be crucial, which aligns with findings from other studies [45, 46]. However, it is worth noting that further exploration is needed regarding the determinants concerning the role of ownership and funding structures, as only a limited number of studies supported the relevance of this determinant in the context of nurse managers' utilization of evidence-informed management. Our review has highlighted the impediments posed by resource-constrained environments to the effective utilization of evidence-informed management. However, it is notable that the dearth of studies addressing this specific context within our review limits a comprehensive understanding of the challenges and strategies pertinent to evidence-informed management utilization in such settings. Moreover, the scarcity of innovative and cost-effective interventions aimed at bolstering the adoption of evidence-informed management underscores the necessity for further inquiry and exploration in this domain [47].

At macrolevel, our review revealed that external stakeholders and the broader socioeconomic, political, and ethical context exert indirect effects on nurse managers' utilization of evidence-informed management. For instance, the functioning of a healthcare facility or organization within

a larger health system that benefits from a favourable socioeconomic environment, such as sufficient funding, a supportive political landscape with policies promoting innovation and leadership, and an ethical context encompassing appropriate legal systems like auditing and health ombudsman, can facilitate the provision of an enabling organizational context for nurse managers. This finding is consistent with previous research [48] that emphasizes the interplay between the macrolevel context and the capacity-building of nurse managers. Consequently, it is crucial to strengthen healthcare systems by developing the capacity to effectively utilize data to measure the impact of interventions, thereby enhancing the utilization of evidence-informed management. This, in turn, leads to improvements in cost-effectiveness and patient outcomes [49]. Once more, it is important to note that the health system strengthening is not solely contingent upon the actions of nurse managers. Nonetheless, the involvement and input of nurse managers are imperative in facilitating their ability to effectively leverage the utilization of evidence-informed management. Empowering nurse managers with decision-making authority and incorporating their perspectives can contribute significantly to the successful integration of evidence-based approaches within health systems [50]. Thus, while nurse managers may not directly influence the strengthening of health systems, their engagement is essential for promoting the utilization of evidence-informed management.

In conclusion, while our review delineated determinants of evidence-informed management across micro-, meso-, and macrolevels, it is imperative to recognize that these determinants do not operate in isolation. Rather, they interact dynamically, constituting an intricate web of factors that collectively influence the utilization of evidence-informed management practices. This holistic perspective underscores the need for a comprehensive understanding of the interplay among various determinants to effectively foster evidence utilization within organizational contexts.

4.1. Limitations. This review has several limitations that should be considered when interpreting the findings. Firstly, the small number of studies related to the facilitation of utilization of evidence-informed management by nurse managers limits in-depth understanding and conclusive evidence on the topic. Secondly, the search for relevant literature was restricted to institutional databases accessible to D.R.C., which may have led to the exclusion of potentially valuable studies from other sources [19]. Thirdly, the inclusion criteria were limited to studies published in English, which may have introduced language bias and resulted in the omission of relevant studies published in other languages [51]. Fourthly, the review included mainly non-experimental studies, primarily comprising Level III evidence, which may serve to limit the strength of the conclusions drawn [21]. Additionally, most of the included studies were conducted in developed country contexts, which may restrict the generalizability of some of the findings to other, resource-constrained healthcare settings or facilities. Despite these limitations, this review can still provide valuable insights in

an underresearched topic such as evidence-informed management. However, researchers should be aware of these limitations and interpret the findings with caution.

4.2. Recommendations for Future Research. It is crucial to recognize the current limitations of published evidence in this field. There is a clear necessity for more robust research to improve the validity and generalizability of findings. This would enable the development of evidence-based strategies and interventions to better support nurse managers in effectively utilizing evidence-informed management practices. Therefore, it is recommended that further research be conducted to enhance the validity and breadth of knowledge on evidence-informed management and how its use could be facilitated among nurse managers. Future studies should employ robust research designs, notably large-scale and meticulously crafted randomized controlled trials, spanning various contexts. This is especially pertinent in resource-constrained healthcare environments where novel approaches are needed to promote the adoption of evidence-informed management practices. Such an approach promises to yield a deeper comprehension of the factors shaping the utilization of evidence-informed management by nurse managers and offer insights into strategies for enhancing its utilization and implementation.

Additionally, it is recommended to conduct a systematic review and/or meta-analysis summarizing the impact of evidence-informed management on managerial and patient care outcomes, as these aspects were not the primary focus of the current review. Synthesizing existing evidence in this manner could provide valuable insights into the broader implications of evidence-informed management practices.

Finally, the studies encompassed within this review notably abstained from delineating precise adaptations or modifications in the utilization of evidence-informed management practices by middle managers amid the pandemic. Such a delineation was not explicitly within the purview of this review. However, it warrants consideration whether there exists a discernible divergence or heightened efficacy attributed to the utilization of such practices amid the pandemic's needs. This assessment is particularly pertinent given the pronounced impact of the pandemic on healthcare and nursing management, and expectations for the role within these sectors.

4.3. Implications for Nursing Management. This study provides guidance to nurse managers in their work practices. The 13 identified determinants can be considered to enhance nurse managers' utilization of evidence-informed management which has the potential to influence organizational outcomes at the micro-, meso-, and macrolevels, but requires organizational support and health system strengthening. The determinants identified could be effectively integrated into daily management practices through a variety of approaches. One such approach involves benchmarking with other health facilities or organizations to strategically enhance the utilization of evidence-informed management among nurse managers. Additionally,

conducting a context analysis can provide insights into which determinants are currently in place and which ones require strengthening to facilitate the seamless integration of evidence-informed management into decision-making processes. This analysis serves as a foundation for developing one or more strategies, complete with defined goals, tasks, timeframes, task prioritization, and clear evaluation criteria [52]. Following the context analysis, the development of strategies may entail the creation of tools, such as educational resources aimed at training nurse managers on evidence-informed management principles, and dashboards designed to streamline the management and analysis of evidence and data [53]. These tools can be adapted from existing resources or developed anew and subsequently incorporated into a comprehensive toolkit to enhance the implementation of strategies prior to pilot testing. Continuous evaluation of the effectiveness of these strategies aimed at optimizing the utilization of evidence-informed management is essential. Feedback loops and the identification of emerging best practices enable the ongoing refinement and adaptation of approaches to ensure their relevance and efficacy in real-world settings [54].

5. Conclusions

This comprehensive review identified a total of 13 determinants that significantly influence the utilization of evidence-informed management by nurse managers. These determinants were organized into three overarching themes: (1) Nurse manager determinants in utilization of evidence-informed management at the microlevel, (2) Organizational determinants in utilization of evidence-informed management at the mesolevel, and (3) External stakeholders and context determinants of utilization of evidence-informed management at the macrolevel. The themes were found to be interconnected and interdependent and can be used by nurse managers to optimally utilize evidence-informed management. However, the findings also highlight the need for executive management and policymakers to strengthen health systems by providing resources and support, such as education, incentives, effective communication, robust organizational structures, funding, and ownership. Future studies from various contexts are required to provide a more comprehensive understanding of the determinants influencing nurse managers' utilization of evidence-informed management practices and the use of interventions and strategies to achieve evidence-informed management.

Background. Global nursing shortages have led to the recruitment of culturally and linguistically diverse nurses from various countries. However, nurses face integration challenges in their host countries. **Objective.** This systematic review aimed to find the most recent evidence of factors associated with integrational strategies and models to support the transition and adaptation of culturally and linguistically diverse nurses to the professional workforce in healthcare settings. **Methods.** This systematic review used the population, exposure, outcome framework to select studies according to JBI guidelines. Original peer-reviewed quantitative studies published between 2000 and 2021 were identified. Two researchers independently screened the studies based on eligibility criteria using title, abstract, and full text. The JBI critical appraisal tool assessed the methodology's quality for analytical cross-sectional studies. Data were extracted, tabulated, and analysed narratively. PRISMA checklist was used in reporting. **Data Sources.** CINAHL (Ebsco), PubMed, Medic, ERIC (ProQuest), and Scopus. **Results.** The systematic review encompassed 19 articles and identified multiple factors associated with successful integration. These factors were classified into the following six categories: sociodemographic characteristics, discrimination, social support, organisational support, workplace environment, and acculturation. **Conclusions.** Comprehensive cultural competency training for healthcare staff, including managers, enhances cultural proficiency in work environments. Clear guidelines addressing bias and discrimination create a supportive environment where culturally and linguistically diverse nurses feel valued and respected, facilitating their adaptation and integration. **Relevance to Clinical Practice.** Patient care quality can be improved by ensuring sustainable culturally and linguistically diverse nurses' integration into healthcare organisations. Cultural diversity is a unique opportunity to bring a diverse range and experience to clinical settings. The diversity can also help enhance the cultural competence of healthcare staff, allowing them to better understand and cater to the needs of culturally diverse patients. **Patient or Public Contribution.** Not required for study design.

1. Introduction

Globally, one in every eight nurses (13% = 3.7 million) were born or trained in a country other than the one in which they currently practise, and this mobility is expected to increase

[1]. Recruitment of culturally and linguistically diverse (CALD) nurses can be considered a strategy to address nursing shortages and bring diverse backgrounds, experiences, and skills that can contribute to filling the gaps in the nursing workforce [1–4]. However, it is creating new

challenges for healthcare organisations [5] and the host nurses who supervise the workplace entry of CALD nurses and assist them in integrating into the health workforce [6]. These challenges include, for example, learning a new language or technical terminology [7], differences in nursing practices and cultural values, discrimination and racism, or delays in recognition of competencies, all of which can lead to deskilling and frustration [8–10]. CALD nurses are often required to adapt and learn, while representatives of the majority population are generally not expected to change in multicultural work communities [4, 11, 12]. Moreover, working communities often have a normative requirement to adhere to established operating models whose contents may not be accustomed to negotiation. Hence, a good nurse with a foreign background has assimilated into the majority population as much as possible. In this case, support of the work community towards CALD nurses appears to be conditional; thus, if the newcomer CALD nurse is considered to be active and positive, the community may support them better [4].

Successful workplace integration is a continuous [13], complex, costly [14], and time-consuming process not only for the organisation but also for internationally trained nurses and host nurses [4, 15–18]. Integration is a two-way adaptation process or goal between the receiving society and the immigrant, as individuals and as a group, ensuring that both parties maintain their cultural identity [16, 19]. In integration, the immigrant commits and becomes accepted into the society of the destination country culturally, politically, and socioeconomically [19]. Factors in the workplace that promote the integration and permanence of CALD nurses are a practical work environment, cooperative work community, support from managers and colleagues, professional development opportunities [18, 20, 21], sociocultural support and training [20], and a desirable work-life balance [18]. Successfully integrated nurses can efficiently lead the work team in work communities, instruct colleagues, and participate in developing high-quality service [13, 17]. On the other hand, the lack of support for integration can cause weakened self-esteem, the feeling of being an outsider, shame, anxiety caused by a different culture, and isolation among immigrant nurses [11, 13].

The factors associated with integration into a different healthcare setting have been shown to impact CALD nurses' personal and professional outcomes significantly [13], patients and their families [22], and thus, the efficiency and profitability of the entire healthcare system [23]. Therefore, any strategies and models developed and implemented must adopt a multidimensional approach, considering factors associated with integrating CALD nurses. Considering these aspects, the integration process can be strengthened, leading to more positive outcomes [20, 24]. Poor workplace integration experience is intrinsically linked to high attrition rates of CALD nurses and concomitantly increasing healthcare costs while compounding existing nursing workforce shortages [25, 26].

There appears to be a lack of previous reviews of understanding the factors related to the integration strategies and models of CALD nurses and the potential for these factors to enhance outcomes during the transition of

immigrant nurses into the professional workforce. The main objective of this review is to seek the latest evidence concerning the factors related to integrational strategies and models, thereby aiming to support the transition and adaptation of CALD nurses within healthcare environments. In addition, this research emphasises the importance of establishing the standards of healthcare organisations associated with the effective integration of CALD nurses.

2. Research Aim

This systematic review sought the most recent evidence on factors associated with integrational strategies and models to support CALD nurses' transition and adaptation to the professional workforce in healthcare settings.

The following research question is addressed: which factors are associated with integrational strategies and models developed to support the transition and adaptation of CALD nurses to the professional workforce in healthcare settings?

3. Methods

3.1. Search Strategy. This systematic review was conducted following the guidelines of the Joanna Briggs Institute (JBI) Manual for Evidence Synthesis—Systematic Review [27]. Systematic reviews aim to establish evidence by synthesising international research, and the results are used to inform practice, policy, evidence-based practice, and research. The advantages of conducting a systematic review are that the findings establish the international scope of practice, help build new practices by either affirming or putting to question current practice, and support clinical decision-making [28]. This method suited our phenomena since CALD nurse integration into healthcare is global, and findings may help improve integrational practices. After identifying the aim of the study and research question [29], participants, exposure of interest, and outcomes' (PEOs) protocol was used to formulate the review inclusion and exclusion criteria [28]. The review participants included CALD nurses from primary and specialised healthcare settings. Primary healthcare settings included general practice, primary care clinics, community health centres, emergency care, and residential older person care facilities. Specialised healthcare settings included hospitals, speciality clinics, rehabilitation centres, and mental health facilities. Students, patients, and healthcare professionals other than nurses were excluded from this study. The exposure of interest was studies that describe factors that predict or are related to integrating CALD nurses into healthcare organisations. The review searched for studies that reported outcomes of CALD nurses' models and strategies for integrating into nursing professional work in primary and specialised healthcare organisations, including orientation and education, team and atmosphere at work, competence evaluation and career development, management and leadership, mentorship, and retention. The review examined original, peer-reviewed, quantitative studies published from 2000 to 2021. The language limitation was set to Finnish and English. Grey

literature was not included. Qualitative studies were excluded from this systematic review since they did not align with the research aim.

The search terms used included synonyms of the population, exposure, outcome (PEO) framework keywords relevant to this study as inclusion criteria [27]. The Oulu University library and researchers in the subject area were consulted to ensure that appropriate databases, search terms, and keywords were included to enhance the validity of the information retrieved for this review. The search was focused on the inclusion criteria and combined with Boolean operators AND, OR, and NOT (see Supplementary File 1).

Five databases were selected to retrieve original studies for the systematic review: PubMed, CINAHL (EBSCO), ERIC (ProQuest), Scopus, and Medic. PubMed stood out for its user-friendly interface and comprehensive content coverage, leading to its selection over Ovid Medline. In addition, Medic, a Finnish health sciences reference database managed by the Helsinki University Library, was considered. It encompasses medical, dental, nursing, and associated bioscience literature alongside selected publications from other pertinent fields. Hosting about 120,000 references, it sees an annual addition of roughly 3,000 new entries, focusing on material published in Finland, irrespective of language [30].

3.1.1. Screening Process and Quality Assessment. A total of 13752 publications were retrieved from the database searches (see Figure 1). Six researchers (authors blinded) participated in the screening process. After 5301 duplicate publications were excluded, the total number of studies included was 8451. The next stage involved screening based on titles and abstracts, during which 7694 studies were excluded. Next, full-text screening of $n=757$ studies was conducted, where 737 papers that did not meet the initial inclusion criteria were eliminated. Each study underwent a double screening, and a third reviewer resolved conflicts. Twenty articles met the inclusion criteria and were subjected to a quality appraisal (see Figure 1).

For quality appraisal assessment, the JBI critical appraisal tool for analytical cross-sectional studies [32] was used to assess the methodological quality of each study ($n=20$) (see Supplementary File 2). This appraisal tool consists of eight evaluation criteria that examine the methodological quality of an article and determine the extent to which a study has addressed potential biases in its design, conduct, and analysis. Each criterion was evaluated and marked as “yes,” “no,” “unclear,” or “not applicable.” One point was assigned for each criterion rated “yes.” Six researchers (authors blinded) were involved in the quality appraisal assessment to ensure rigorous assessment. Each study underwent a double assessment separately, and disagreements were discussed and resolved through consensus. Inclusion in the review required meeting at least four of the eight requirements, with a total score of at least 50%. Low-quality studies were excluded to maintain the validity of the review’s results and recommendations.

Furthermore, 19 studies scored above 50% and were included in the data synthesis. Among these, three studies

scored 100%, six scored 75%, seven scored 62.5%, three scored 50%, and one scored 37.5% (excluded from data synthesis). Most of the articles received lower quality scores for various reasons, such as uncertainty regarding the valid and reliable measurement of exposure, lack of clear identification and strategies to address confounding factors, and uncertainty regarding the valid and reliable measurement of outcomes.

3.2. Data Extraction and Analysis. The 19 original studies selected were organised by year of publication, country of origin, purpose, methodology (study design, instruments, data collection, and data analysis), participants, and factors associated with the integration and quality assessment score [27] (Table 1). Furthermore, the studies identified and presented the factors most significantly associated with integrating CALD nurses. A narrative synthesis approach was used to synthesise the data [33]. This involved collecting all the narrative results from the selected studies, reducing the data by identifying similarities and dissimilarities, and organising similar findings into meaningful classifications.

4. Results

The factors associated with integrating CALD nurses in healthcare organisations were explored in 19 of the original studies. The original studies selected for the systematic review were published between 2008 and 2021 and conducted in the United States (US) (six reviews), United Kingdom (UK) (3), Saudi Arabia (1), Canada (2), Taiwan (4), Korea (1), and Australia (2). The designs of the selected studies were descriptive ($n=7$), cross-sectional ($n=11$), and comparative ($n=1$), and data collection methods that included survey questionnaires and electronic databases were used. The data analysis methods used were statistical parametric analysis and descriptive nonparametric analysis. Participants in the original studies were internationally recruited registered nurses from different countries working as registered nurses in the US, UK, Canada, Australia, Saudi Arabia, and Taiwan. The number of participants varied from 15 to 1951. The systematic review provided an overview of the findings from each study in terms of the factors related to the integration of CALD nurses in healthcare organisations. The data are divided into the following six categories that aimed to answer the research question: (1) sociodemographic characteristics, (2) discrimination, (3) social support, (4) workplace environment, (5) organisational support, and (6) acculturation (see Table 2). The factors influencing integration were classified based on Kamau et al.’s [20] three-dimensional model of integration models and strategies. This model incorporates professional development characteristics, intraorganisational factors, and sociocultural aspects categorised accordingly.

4.1. Factors Associated with Professional Development

4.1.1. Career and Competence Development. Statistically significant individual characteristic factors related to the career and competence development of internationally

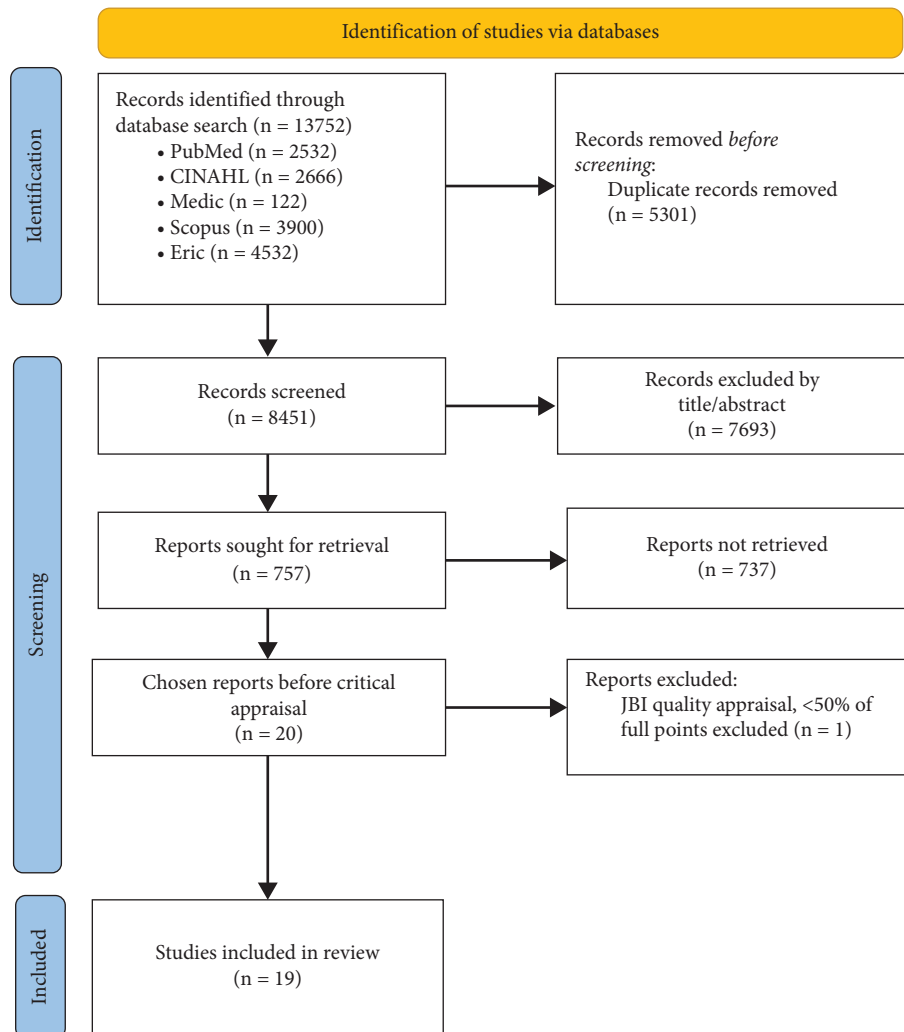

FIGURE 1: Prisma flow diagram [31].

educated nurses (IENs) include their birth year, gender, parenting responsibilities, visible minority status, and level of education. According to Primeau et al. [34]; in a study conducted on the career satisfaction of IENs in Canada, it was found that older and more experienced IENs tended to be more satisfied with their careers compared to their younger or less experienced counterparts ($p < 0.01$). In addition, women expressed higher levels of career satisfaction in the nursing field compared to men ($p < 0.05$). Furthermore, IENs with children under 16 were more satisfied ($p < 0.05$) with their careers than those without parental responsibilities. Men with children reported significantly higher satisfaction levels than women without children ($p < 0.05$). The study also revealed a distinction between visible minority groups ($p < 0.01$), with White and Asian individuals showing significantly higher levels of satisfaction ($p < 0.05$) compared to Black individuals, who tended to be the least satisfied. IENs with nonuniversity degrees before immigrating to Canada exhibited higher career satisfaction ($p < 0.01$) than those with undergraduate degrees, master's degrees, or PhDs. Similarly, the study indicated that higher levels of education attained before

immigrating were associated with lower levels of career satisfaction.

Significant differences were observed in education factors in the USA. There was a notable association between IENs and their enrolment in a degree programme after acquiring licensure ($p = 0.01$) as well as their pursuit of advanced academic degrees ($p = 0.02$) compared to nurses educated in the US (UENs). It was found that twice as many UENs ($n = 54$, 38%) obtained an additional degree following their licensure compared to IENs ($n = 10$, 19%). [35].

Primeau et al. [34] revealed that career characteristics substantially influence career and competence development. It was found that IENs who worked full time showed significantly higher satisfaction levels than those who worked part time or occasionally ($p < 0.01$). In addition, there were notable differences among nursing professions, with registered nurses and registered psychiatric nurses reporting significantly higher satisfaction levels than licensed practical nurses ($p < 0.01$). Furthermore, IENs differed significantly from their host nurses in terms of their practice roles ($p = 0.03$), predominantly working as staff nurses ($n = 52$, 98%) with fewer leadership responsibilities ($n = 1$, 2%).

TABLE 1: Data extraction.

Author(s), year of publication, country	Purpose	Methodology: study design, instruments, data collection, data analysis	Participants	Factors associated with integration	Quality assessment
Adeniran et al., 2013, USA	To determine differences between internationally educated nurses and nurses educated in the United States in their levels of mentoring functions, self-efficacy, and participation in professional development and career advancement	<p>A descriptive design, cross-sectional</p> <p>(1) Mentorship measure. (2) New General Self-Efficacy Scale. (3) Demographic questionnaire</p> <p>A web-based survey</p> <p>A power analysis, descriptive statistics, frequency and percentage estimates for categorical variables, mean, standard deviations, <i>t</i>-tests, Chi-square analyses</p>	<p><i>n</i> = 200 registered nurses (educated in the United States <i>n</i> = 145, internationally educated nurses <i>n</i> = 55), age 22–65 years, currently working in hospital settings for a minimum of 3 years within Philadelphia County</p>	<p>The level and quality of mentorship functions received by internationally educated nurses (IENs) were insufficient for them to advance to leadership positions as their counterparts' nurses educated in the United States (UEN).</p> <p>Significant disparities were noted in the role model function of mentoring (<i>p</i> = 0.02). Mentors for IENs were more ethnically diverse and less likely to hold leadership positions in their organisations. IENs (<i>n</i> = 10.18%) were half as likely to pursue another degree compared with UENs (<i>n</i> = 51.36%). UENs were significantly different from IENs in their practice role (<i>p</i> = 0.03). They reported receiving promotions significantly more frequently than IENs (<i>p</i> = 0.04). IENs worked predominantly as staff nurses (<i>n</i> = 52.98%), with a mere one IEN reporting working in the area of leadership (<i>n</i> = 1.2%). Practice roles among UENs were more diverse (<i>n</i> = 28.21%)</p>	8

TABLE 1: Continued.

Author(s), year of publication, country	Purpose	Methodology: study design, instruments, data collection, data analysis	Participants	Factors associated with integration	Quality assessment
Alexis, 2014, UK	To determine internationally registered nurses' perception of discrimination, support, and their adjustment to a new environment in the National Health Service in England	<p>A descriptive design.</p> <p>(1) Discrimination. (2) Support. (3) Adjustment to a new environment</p> <p>A paper survey was constructed following the emergent themes from the qualitative data analysis</p> <p>Chi-square, Fisher exact, Kruskal–Wallis test</p>	<p>$n = 188$ internationally recruited registered nurses from 15 National Health Service Hospitals in England who be working for a minimum of 1 year, Black or of minority ethnic origin and had to be qualified as an international nurse</p>	<p>International registered nurses (IRNs) perceived that they were discriminated against in the workplace ($p < 0.00$) and patients and family members behaved difficultly and aggressively toward them ($p < 0.00$). IRNs perceived that White British nurses were aggressive towards them for a reason based on their racial features ($p < 0.01$). IRNs felt supported in their workplaces ($p < 0.01$). IRNs from Africa perceived discrimination as evident in the workplace; the support they received was limited, and their adjustment to a new environment was the weakest compared to the other IRNs</p>	4

TABLE 1: Continued.

Author(s), year of publication, country	Purpose	Methodology: study design, instruments, data collection, data analysis	Participants	Factors associated with integration	Quality assessment
Alexis and Vydellingum, 2009, UK	To determine how overseas nurses perceive equal opportunities as well as the opportunities for skill development and training to be in the National Health Service in the United Kingdom	<p>A descriptive design, a questionnaire approach.</p> <p>(1) Biographical information for example grade. (2) Years of experience in their country of origin and the national health service. (3) Equal opportunity. (4) Discrimination. (5) Support mechanisms. (6) Adjustment to a new environment. (7) Skill development and training</p> <p>A survey approach was adopted to investigate the aims of the study</p> <p>A simple descriptive statistics, Chi-squared tests, Fisher's exact tests, Kruskal-Wallis tests, Mann-Whitney <i>U</i> tests, Spearman's tests</p>	<p><i>n</i> = 188 registered nurses and qualified as overseas nurses, black and minority ethnic origin, and be working in the National Health Service in the United Kingdom for a minimum of one year</p>	<p>Overseas nurses from African nurses perceived that were refused jobs based on their ethnic backgrounds whereas Filipino nurses were less likely to perceive this. Nurses from India and Pakistan were more likely to be promoted than any other group of international nurses. African nurses were more likely to perceive that they had been refused promotion based on their ethnicity. Filipino nurses indicated that their skills were more likely to be used than those of their African counterparts. In addition, the survey revealed that overseas nurses employed in NHS hospitals in London were more likely to be promoted and supported and less likely to have aggressive behaviour directed at them compared to those in NHS hospitals in non-London regions</p>	5
Almansour et al., 2020, Saudi Arabia	To investigate whether there is an association between nationality and nurse job satisfaction	<p>A cross-sectional design</p> <p>(1) McCloskey/Mueller Satisfaction Scale</p> <p>An online survey and a paper survey</p> <p>Preliminary analysis, a multiple linear regression analysis, a descriptive analysis</p>	<p><i>n</i> = 743 nurses from three major Government Hospitals in Saudi Arabia</p>	<p>Non-Saudi nurses had lower satisfaction rewards such as pay, holiday entitlement, and work/life balance. Compared with Saudi nurses, expatriate nurses had overall lower job satisfaction after controlling for other predictors. Expatriates were less satisfied than Saudi nurses with extrinsic rewards and family-work balance. However, Saudi nurses were less satisfied with their professional opportunities, praise and recognition, and coworker relationships</p>	8

TABLE 1: Continued.

Author(s), year of publication, country	Purpose	Methodology: study design, instruments, data collection, data analysis	Participants	Factors associated with integration	Quality assessment
Bae, 2011, USA	To examine international nurses' perceptions of their organizational socialization and its association with intent to leave in both international and American nurses	<p>A descriptive design, secondary analysis of data from a hospital registered nurses survey</p> <p>(1) Organizational socialization (the quality of the orientation programme and support from supervisors and peers). (2) Nurses' intent to leave (within three years). (3) Nurses' country of origin</p> <p>A paper survey, an online survey</p> <p>Analysis of variance and Chi-square tests, a logistic regression model</p>	<p>$n = 752$ registered nurses ($n = 245$ international registered nurses, $n = 507$ American registered nurses) in the greater New York metropolitan area with less than five years of registered nurse experience in the USA</p>	<p>The orientation programme and support from peers and supervisors played an important role in the international nurse's organizational socialization process. Good supervisor and peer support were negatively associated with nurses' intent to leave (i.e., these nurses were less likely to leave within three years). The level of organizational socialization of foreign-educated RNs was higher than that of any other nurse groups, especially when looking at the item entitled "hospital provided adequate orientation" ($p < 0.01$). Lower proportions of the foreign-educated RNs (26%) and adult immigrant RNs (29.1%) reported that they had plans to leave within three years compared to American RNs (45.2%) and child immigrant RNs (39.3%)</p>	6
Butt et al., 2019, UK	To describe the employment outcomes of a refugee healthcare professional who participates in the Building Bridges Programme in the United Kingdom National Health Service	<p>A comparative design, statistical and contractual reporting</p> <p>(1) Employment outcomes. (2) (%) proportion of refugee healthcare professionals joining the Building Bridges Programme who settle in an associated healthcare profession position</p> <p>An electronic database</p> <p>Statistical and contractual reporting</p>	<p>$n = 83$ refugee nurses who participated in the Building Bridges Programme from October 2009 to March 2018 and sought employment in the UK National Health Service</p>	<p>The Building Bridges Programme provides 2/83 (2%) nurses settled into a registered National Health Service position appropriate to their (home country) professional qualifications. 34/83 (41%) nurses settled in associated healthcare profession positions</p>	4

TABLE 1: Continued.

Author(s), year of publication, country	Purpose	Methodology: study design, instruments, data collection, data analysis	Participants	Factors associated with integration	Quality assessment
Cheng and Liou, 2010, Taiwan	To measure the predictability of cultural orientation on organisational commitment, perception of practice environment, and intention to leave amongst Asian nurses working in US hospitals	A cross-sectional design, postsurvey. (1) The Organisational Commitment Questionnaire. (2) Practice Environment Scale of the Nursing Work Index. (3) Anticipated Turnover Scale. (4) Collectivist Orientation Scale with satisfactory reliability A postal survey descriptive statistics, hierarchical regression, Pearson correlation, Mann-Whitney <i>U</i> -test, Sobel-test	<i>n</i> = 195 Asian nurses (44.1% Filipinos, 32.8% Chines) working at least six months in US hospitals	Organisational commitment is a key predictor of Asian nurses' intention to leave. Asian nurses who are more collectivist-oriented are more willing to accept the goals and values of the organisation, exert effort on behalf of the organisation, are more satisfied with their current practice environment and have less intention to leave their current job	5
Covell et al., 2018, Canada	To examine internationally educated nurses' perceptions of the extent to which participating in bridging programmes is beneficial for preparing to practise nursing in Canada	A cross-sectional design (1) Demographics. (2) Perceived benefits of bridging program participation (B ² P ⁻²)-scale descriptive statistics, linear multiple regression analysis	<i>n</i> = 360 internationally educated nurses who participated in bridging programmes, and live and work permanently as a nurse in Canada	Bridging programmes help internationally educated nurses address gaps in their cultural, practical, and theoretical knowledge. Source country and amount of professional experience influence the extent to which internationally educated nurses benefit from participating in bridging programmes in Canada. The regression model explained 11.5% of the variance in perceived benefits of bridging programme participation. Two predictors were statistically significant: source country and professional experience	8
Geun et al., 2018, Korea	To investigate factors affecting the turnover of Asian Foreign-educated nurses	A cross-sectional design (1) Supplement digital content 1 and 2. (2) Organizational Commitment Questionnaire. (3) McCain and Marklin Social Integration Scale. (4) Confidence and communication. (5) Job search self-rated health instrument: an online survey backward multivariable logistic regression	<i>n</i> = 201 Asian foreign-educated nurses in their 1 st year of employment in the United States	Perceived quality of orientation and affective commitment were the only significant predictors of turnover at the organizational level of Asian foreign-educated nurses. Perceived quality of orientation predicted organizational-level turnover and trended toward predicting unit-level turnover	6

TABLE 1: Continued.

Author(s), year of publication, country	Purpose	Methodology: study design, instruments, data collection, data analysis	Participants	Factors associated with integration	Quality assessment
Goh and Lopez, 2015, Singapore	To examine the acculturation level of international nurses working in a multicultural society. The relationship between acculturation, working environment, and quality of life of international nurses was also explored	A cross-sectional, correlational study (1) World Health Organisation Quality of Life-BREF. (2) Practice Environment Scale of the Nursing Work Index-Revised A paper self-report questionnaire Descriptive statistic, histogram and QQ plot, mean score and deviation, a Pearson product-moment correlation coefficient	$n = 814$ international nurses working in Singapore	There were variations in the acculturation level among different nationality groups of international nurses. Acculturation levels were the lowest among mainland Chinese international nurses ($M = 27.47$, $SD 5.23$). A positive correlation was found between acculturation and quality of life whereas a lower perception of the work environment was associated with a lower acculturation level The presence of a supportive work environment is essential to retain migrant nurses. The results showed that migrant nurses were satisfied with their jobs, with job satisfaction negatively correlated with the work environment. Pre-existing groups of Chinese migrant nurses did not help newly arrived Chinese migrant nurses assimilate better. Predictors of migrant nurses' intentions to leave included having supportive nurse managers and a nursing practice environment Investment in promoting the well-being of recruited nurses, as illustrated by the significant planning effort and strategies employed by this organization, pays off in job satisfaction, and spills over into other areas of satisfaction and positive adaptation. Investing in promoting the well-being of recruits in both social and work contexts positively benefits job satisfaction and spills over into related areas of satisfaction and positive adaptation	6
Goh and Lopez, 2016, Singapore	To explore the job satisfaction level of migrant nurses working in a multicultural society and the relationship between their job satisfaction levels, work environment, their intentions to leave, and the predictors of their intentions to leave	A cross-sectional, correlation design using a stratified random sample (1) A demographic sheet. (2) The job satisfaction questionnaire (JSQ). (3) The practice environment scale-nursing work index-revised A survey A histogram prior, descriptive statistic, mean and standard deviations, a Pearson correlation coefficient analysis	$n = 495$ migrant nurses working in a tertiary public-funded hospital in Singapore for at least one year		5
Hayne et al., 2009, USA	To examine strategies to facilitate the cultural adaptation, job satisfaction, and perception of role and social support of a group of recruited Filipino nurses	A descriptive design (1) The nursing work index-revised edition. (2) Occupation stress inventory-revised edition A survey Normative statistic	$n = 15$ Philippine nurses who were recruited to the USA in 2003 and 2004		6

TABLE 1: Continued.

Author(s), year of publication, country	Purpose	Methodology: study design, instruments, data collection, data analysis	Participants	Factors associated with integration	Quality assessment
Liou et al., 2013, Taiwan	To examine the relationship between acculturation, collectivist orientation, and organisational commitment among Asian nurses in US hospitals	A cross-sectional design using snowball sampling (1) The collectivist orientation scale. (2) Organisational commitment questionnaire. (3) Acculturation factors A paper survey A power analysis Pearson correlation, ANOVA, and regression	<i>n</i> = 195 east Asian nurses working in hospitals across the United States at least six months and performing direct patient care	To increase Asian nurses' commitment, administrators must understand their cultural values and provide them with a culturally competent and sensitive environment. Participants scored high on collectivism and commitment. Collectivism was significantly correlated with commitment but did not mediate acculturation factors and commitment	6
Liou and Grobe, 2008, Taiwan, Texas	To examine the relationship among collectivist orientation, perception of practice environment, organizational commitment, and intention to leave	A cross-sectional, correlational design snowball sampling (1) Collectivist Orientation Scale. (2) The Practice Environment Scale of the Nursing Work Index. (3) The Organizational Commitment Questionnaire. (4) Anticipated Turnover Scale Questionnaire Descriptive statistics, Pearson correlation and regression	<i>n</i> = 35 Asian nurses work in U.S. Hospitals	To prevent Asian nurses from leaving employment settings, increasing their organizational commitment appears to be indicated. Because perception of the practice environment is an antecedent of organizational commitment, providing a practice environment where nurses are satisfied is an alternative strategy to retain nurses. Organizational commitment mediates the perception of the practice environment and the intention to leave	5

TABLE 1: Continued.

Author(s), year of publication, country	Purpose	Methodology: study design, instruments, data collection, data analysis	Participants	Factors associated with integration	Quality assessment
Ma et al., 2010, USA	To identify the demands of immigration among Chinese nurses who have immigrated to the USA. The relationship between the demands of immigration and length of stay in the USA was also investigated	A descriptive correlational study design (1) The demands of immigration scale. (2) Demographic questionnaire A self-administered survey frequency distributions, range, descriptive statistics	$n = 128$ Chinese nurses and immigrated to the USA	The immigration demands decreased as the length of stay in the USA increased. Still, the demands of immigration levels remained high for Chinese immigrant nurses compared to the Indian and Filipino nurses. Chinese immigrant nurses have high demands for immigration. There was a significant negative relationship between the demands of immigration and the length of stay in the USA. Immigration demands decreased as the length of stay increased but remained high even for those who had been in the USA for >5 years	5
Pittman et al., 2014, USA	To determine whether foreign educated nurses perceived they were treated equitably in the U.S. workplace during the last period of high international recruitment from 2003 to 2007	A descriptive design Four outcomes of interest. (1) Hourly wages. (2) Job satisfaction. (3) Adequacy of orientation. (4) Perceived discrimination An online survey Descriptive and regression analysis	$n = 629$ foreign-educated nurses in the USA	Foreign-educated nurses educated in low-income countries and those recruited by staffing agencies were significantly more likely than other foreign-educated nurses to report that they receive inequitable treatment compared with their U.S. counterparts. 40% of the foreign-educated nurses in this study perceived their wages, benefits, or shift or unit assignments to be lower than those of their American colleagues. Respondents from high-income countries were significantly less likely to perceive discrimination than respondents from low-income countries. 51% of respondents reported receiving insufficient orientation and 40% reported at least one discriminatory practice regarding wages, benefits, or shift or unit assignments	4

Primeau et al., 2021, Canada	To identify the main correlates of internationally educated nurses' career satisfaction	<p>A cross-sectional analysis</p> <p>The instrument developed for the study includes four sections. (1) Eligibility (2) Integration. (3) Career advancement. (4) Demographics</p> <p>A survey electronically or on paper</p> <p>Kruskal–Wallis test, Spearman rank correlation test, and Mann–Whitney <i>U</i> test</p>	<p><i>n</i> = 1951 internationally educated nurses in Canada</p>	<p>Older and more experienced internationally educated nurses tended to be more satisfied with their careers than their younger or less experienced colleagues were. Males were inclined to be less satisfied than their female counterparts, and having children tended to make all three groups more satisfied. The higher level of education before immigrating the lower the career satisfaction. As for organizational characteristics, full-time nurses were more satisfied than those working part time or with occasional employment. Career satisfaction varied greatly depending on sociodemographic characteristics, organizational settings, and geographic location. Internationally educated nurses who identified as White or Asian had the highest level of career satisfaction, whereas those who identified as Black tended to be the least satisfied. Internationally educated nurses who thought they had achieved their career goals were more satisfied, while those who experienced discrimination were less satisfied with their careers</p>	5

Timilsina Bhandari and Xiao, 2014, Australia	To explore factors associated with the job satisfaction of overseas qualified nurses working in public hospitals in South Australia and to compare whether factors associated with job satisfaction of overseas nurses from English-speaking backgrounds differed from those from non-English-speaking backgrounds	A cross-sectional survey design (1) Job satisfaction of overseas-qualified nurses: index of work satisfaction, nursing work index-R, Mueller, and McCloskey satisfaction scale A survey Kolmogorov-Smirnov test, A Mann-Whitney U-test, Chi-square test, Spearman's correlation, content analysis	<i>n</i> = 151 overseas qualified nurses who work in five major public hospitals in South Australia	Four factors were found to influence job satisfaction: a supportive work environment, interpersonal relationships, communication in English, and salary and salary-related benefits. Communication in English was the predominant factor that was associated with job satisfaction in nurses from non-English-speaking backgrounds. This group of nurses also showed a negative correlation between length of stay in Australia and satisfaction with their work environment. Participants' responses to open-ended questions revealed issues relating to discrimination and racism Job satisfaction and feeling supported in the workplace are the most important factors influencing OQNs' successful adjustment into the Australian healthcare system. Three factors (job satisfaction, current work environment, and feeling at home in Australia) were found to be significant in measuring OQN's level of sociocultural adaptation. When the level of sociocultural adaptation was high, OQNs reported better general and psychological health	5
Zanjani et al., 2020, Australia	The primary aim was to examine factors associated with overseas qualified nurses' sociocultural adjustment to the Australian healthcare system. A secondary aim was to determine whether there was a correlation between overseas qualified nurses' sociocultural adjustment and their mental and physical health	A cross-sectional study (1) Sociocultural adaptation scale-revised. (2) The nurse international and transition questionnaire-2. (3) The perceived stress scale and general health questionnaire-12 A survey electronically Linear regression analysis, the Pearson correlation	<i>n</i> = 200 overseas qualified nurses working as registered nurses in the Australian healthcare system. Participants' English was not their first language and had completed the bridging courses offered in Australia before being granted nursing registration		6

Self-rated health: poor				

Statistical significance has been marked in bold, *p* values <0.05.

Moreover, IENs who believed they had achieved their career goals experienced higher satisfaction levels ($p < 0.01$), while those who faced discrimination expressed lower satisfaction with their careers. The study also highlighted that the first year at the current employer and position had a negative association with career satisfaction. At the same time, there was a moderate and positive association with achieving career goals, all at a significant level of $p < 0.001$. Furthermore, the findings revealed a significant difference in promotions, with UENs reporting a significantly higher frequency of promotions than IENs ($p = 0.04$). In comparison to UENs ($n = 38, 28\%$), a higher proportion of IENs ($n = 20, 41\%$) indicated that they had never received a promotion [35].

Alexis et al. [36] investigated how overseas nurses perceive equal opportunity in the UK. Their study found that African nurses ($p < 0.001$) were more likely to perceive discrimination regarding job refusals based on their ethnic backgrounds. In contrast, Filipino nurses were less likely to have such perceptions. On the other hand, nurses from India and Pakistan had a higher likelihood of being promoted than other groups ($p < 0.001$). In contrast, African nurses were likelier to perceive that they were denied promotions due to ethnicity ($p < 0.001$). Also, geographical location plays a significant role in the perception of ethnic-based denial of promotions ($p < 0.008$).

Primeau et al. [34] found that integration process characteristic factors—a year of immigration ($p < 0.01$), year of the first job ($p < 0.01$), and year of licensure ($p < 0.01$)—were negatively correlated with the job satisfaction of IENs. These results highlight the importance of acculturation and workplace integration with higher levels of job satisfaction among highly qualified immigrants.

When examining organisational characteristics, it becomes evident that IENs working in hospitals experience higher satisfaction levels than those working in long-term care facilities ($p < 0.05$). IENs who perceive themselves as being given fewer opportunities than host nurses or encountering discrimination report significantly lower satisfaction levels ($p < 0.01$). In addition, geographical location plays a role in career satisfaction, with significant variations observed ($p < 0.01$). Furthermore, factors such as mentorship ($p < 0.01$), leadership ($p < 0.01$), promotion ($p < 0.01$), and development ($p < 0.01$) have been identified as significantly correlated with the career satisfaction of IENs [34].

4.1.2. Workplace Mentorship and Preceptorship. The study conducted by Adeniran et al. [35] revealed that the level and quality of mentoring received by IENs were deemed insufficient for their advancement to leadership positions compared to that of their counterparts, UENs. Notably, mentors for IENs were found to be more ethnically diverse ($p < 0.001$) and less likely to hold leadership positions within their organisations ($p = 0.01$) compared to UEN mentors. In addition, IENs were less inclined to view their mentors as role models ($p = 0.02$).

4.1.3. Licensure and Orientation to Work. When examining training factors, Butt et al. [37] investigated the perceived benefits of participation in the Building Bridges Programme

among refugee healthcare workers. The Building Bridges Programme is designed to help refugee healthcare workers fill gaps in their cultural, practical, and theoretical knowledge to support them in finding employment. The study findings indicate that among the program participants, 2% could secure registered positions that matched their professional qualifications from their home country, while 41% obtained positions in related healthcare fields. Furthermore, a related study by Covell et al. [38] discovered that specific factors influenced the perceived benefits of participating in a comparable bridging programme. Notably, the classification of the source country as low income ($p < 0.01$) and the IENs having fewer years of professional experience ($p < 0.01$) were associated with a higher perception of benefits from the Bridging Programme. The regression model employed in the study accounted for 11.5% of the variance in the perceived benefits of participating in the Bridging Programme.

The study conducted by Alexis et al. [36] found significant statistical differences in the level of dissatisfaction concerning the number of attended training courses and grades among overseas nurses compared to their white host country counterparts ($p < 0.001$). The research also found disparities in the availability of training course opportunities based on ethnicity and grades ($p < 0.002$).

4.2. Factors Associated with Intraorganisational Strategies

4.2.1. Collegial and Peer Support. Alexis's [12] study aimed to investigate the perception of perceived discrimination and ethnicity among international registered nurses (IRNs) in the UK. The findings of the study revealed that IRNs perceived instances of discrimination within the workplace ($p < 0.001$). Specifically, African nurses were more likely to perceive discrimination than nurses from India and Pakistan. In addition, the study highlighted that White British nurses were perceived as exhibiting difficult, aggressive, or hostile behaviour towards IRNs based on their ethnicity ($p < 0.001$).

Furthermore, the study also investigated the perception of social support among IRNs in the UK. It was found that IRNs generally felt supported in their workplace ($p < 0.001$), with both Indian and Pakistani nurses perceiving higher support levels than their international counterparts. On the other hand, African nurses reported receiving the least amount of support in the working environment. Notably, IRNs acknowledged receiving assistance from their White British colleagues, which was statistically significant ($p < 0.01$). Similarly, Alexis et al.'s [36] study supported the findings that experiences of discrimination in the UK varied based on race and ethnicity. Specifically, Black minority IENs were more likely to experience discrimination than Asian-Pacific and Caucasian IENs [12].

4.2.2. Workplace Environment, Diversity, and Employee Treatment. A healthy work environment was found to positively impact the career development of IENs, while poor work environments act as barriers to their career

advancement [34, 35]. The research conducted by Goh and Lopez [39] demonstrated that job satisfaction among migrant nurses in Singapore was negatively correlated with the work environment. The study further indicated that international nurses with lower reported acculturation levels also reported lower perceptions of their work environment. Predictors of IENs' intentions to leave their current positions included having supportive nurse managers ($p = 0.03$) and a favourable nursing practice environment ($p = 0.01$). Also, the study found ethnic differences and Indian nurses reported the highest level of job satisfaction, followed by Malaysian, Filipino, Myanmar, and Chinese nurses. Almansour et al. [40] aimed to investigate the link between nationality and nurse job satisfaction in Saudi Arabia. The study findings indicated that Saudi nurses reported higher levels of satisfaction compared to non-Saudi nurses (IENs) regarding extrinsic rewards ($p < 0.005$) and achieving a work-life balance ($p < 0.005$). Conversely, IENs expressed greater satisfaction than Saudi nurses in areas such as co-worker relationships ($p < 0.005$), professional opportunities ($p < 0.005$), and receiving praise and recognition ($p < 0.005$).

The study conducted by Timilsina Bhandari et al. [41] demonstrated that communication in English ($p = 0.001$) emerged as the predominant factor associated with job satisfaction among nurses from non-English-speaking backgrounds. In addition, overseas nurses exhibited a negative correlation between the duration of their stay ($p < 0.05$) in Australia and their satisfaction with the work environment. Interestingly, the longer overseas-qualified nurses remained employed in Australia, the less satisfied they became.

Organisational socialisation demonstrated a significant negative correlation with the intention of IRNs to leave within three years ($p < 0.01$). This indicates that IRNs who reported higher levels of organisational socialisation were less likely to leave their current positions within three years. Specifically, two aspects of organisational socialisation—that is, being treated as a colleague by peers ($p < 0.05$) and receiving support from supervisors ($p < 0.01$)—were found to be negatively associated with nurses' intention to leave. Notably, the level of organisational socialisation among IRNs was higher compared to those among other nurse groups, particularly in terms of the item assessing whether the hospital provided adequate orientation ($p < 0.01$) [42].

Geun et al. [43] examined the factors influencing the turnover of Asian foreign-educated nurses in the USA. The findings revealed that perceived quality of orientation ($p < 0.001$) and affective commitment ($p < 0.001$) were significant predictors of turnover at the organisational level. Specifically, the perceived quality of orientation predicted turnover at the organisational level and revealed a trend in predicting turnover at the unit level ($p = 0.01$). Additionally, preparatory job search behaviours ($p = 0.04$) and active job search behaviours ($p = 0.05$) were associated with unit-level turnover.

Alexis [12] study revealed that IENs *perceived discrimination* in the workplace, specifically from patients and their family members ($p < 0.01$). The data further indicated that African nurses were more inclined to perceive such

discrimination than the other three groups of IENs. Further, Pittman et al. [44] discovered that IENs experienced discrimination and expressed concerns regarding the disparity in pay ($p < 0.01$) and benefits ($p < 0.01$) compared to their US counterparts. The study revealed that 51% of the IENs reported insufficient orientation, while 40% reported facing at least one discriminatory practice ($p < 0.01$) related to wages, benefits, or shifts/assignments. Compared to other IENs, IENs educated in low-income countries and those recruited through staffing agencies were more likely to report receiving unfair treatment than their US counterparts ($p < 0.05$). In addition, IENs recruited through staffing agencies reported significantly lower wages than self-employed IENs ($p < 0.05$), and the wages were found to be approximately 14% higher for IENs educated in high-income countries compared to those educated in low-income countries.

Liou et al. [45] conducted a study investigating the relationship between acculturation, *collectivist orientation*, and organisational commitment among Asian nurses in hospitals in the US. The findings revealed a significant correlation between collectivism orientation and organisational commitment ($p = 0.001$). Participants born in Asian countries other than the Philippines demonstrated lower levels of organisational commitment. In addition, in a study by Cheng and Liou [46], it was discovered that organisational commitment ($p < 0.001$) serves as a significant predictor of the intention of Asian nurses to leave their positions in US hospitals. Moreover, Asian nurses with a stronger collectivist orientation are more willing to embrace the organisation's goals and values, experience higher satisfaction with their current work environment, and display a reduced intention to leave their current job.

The research conducted by Ma et al. [47] demonstrated that Chinese immigrant nurses had a high demand for immigration. It was observed that there was a significant negative relationship ($p = 0.01$) between the demands of immigration and the duration of stay in the US. As the duration of stay increased, the demands of immigration decreased, but even among those who had been in the US for over five years, the demands remained relatively high.

4.2.3. Organisational and Management Support and Policies.

The study conducted by Alexis et al. [36] found that African IENs, in particular, were unaware of their employers having an equal opportunity policy ($p < 0.001$). In addition, IENs working in London hospitals perceived equal opportunity policies as more effective than nurses in non-London hospitals ($p < 0.001$). Moreover, Filipino nurses expressed a higher likelihood of their skills being utilised than their African counterparts ($p < 0.002$).

4.3. Factors Associated with Sociocultural Integration.

In a study conducted by Zanjani et al. [48], job satisfaction and integration process characteristic factors were identified as influencing the sociocultural adjustment of IENs to the Australian healthcare system; job satisfaction ($p < 0.01$), current work environment ($p = 0.02$), and a sense of feeling

at home ($p = 0.01$). When IENs achieved a high level of sociocultural adaptation, they reported better overall health and physical well-being. The study also highlights the primary motivations that drove IENs to relocate to Australia. The dominant pull factors were creating a better life for their families (68.5%), improving their financial situation (56.5%), and perceiving political stability (49%) in their new country. Conversely, the main push factors that influenced their decision to leave their home countries were low pay (71.5%) and a lack of opportunities for further nursing education (68%).

According to the findings of Goh and Lopez's [49] study, mainland Chinese IENs working in Singapore exhibited the lowest levels of acculturation. The study also revealed a positive correlation ($p < 0.01$) between acculturation and quality of life, thereby indicating that higher levels of acculturation were associated with a better perception of one's overall well-being. Conversely, a lower perception of the work environment was linked to lower levels of acculturation. In a study by Hayne et al. [50], the researchers examined strategies to help Filipino nurses adapt to cultural aspects after being recruited in the US. The findings indicate that investing in promoting the well-being of recruits in social and work contexts positively impacts job satisfaction and extends to other areas of satisfaction and positive adaptation.

5. Discussion

This systematic review identified multiple factors associated with the successful integration of CALD nurses, thereby highlighting their impact on integration strategies and models. These factors were classified into the following six categories: sociodemographic characteristics, discrimination, social support, organisational support, workplace environment, and acculturation.

Numerous factors influence job satisfaction and can vary in cultural contexts and value systems. Low job satisfaction among CALD nurses significantly contributes to high turnover rates, eventually impacting the quality and safety of patient care [51]; [52, 53]. The findings of this review indicate that a range of factors can influence job satisfaction among CALD nurses. The work environment plays a vital role in the job satisfaction and career development of CALD nurses. Factors such as having supportive colleagues, supervisors, and mentors, receiving equal treatment as employees, having access to adequate resources and educational opportunities, and being part of a positive team culture significantly contribute to the overall job satisfaction of CALD nurses. Thus, the findings of this study demonstrate that individual characteristics (age, gender, parenting responsibilities, ethnicity, and education) with factors related to career development, organisational characteristics, and the integration process collectively influence job satisfaction among CALD nurses.

In addition, the findings indicated variations in job satisfaction among different racial and ethnic groups, with Black minority nurses demonstrating lower levels of job satisfaction than their White counterparts. Creating

a supportive and inclusive work environment that respects and recognises their characteristics can further enhance the job satisfaction of CALD nurses [51]. When nurses feel valued, respected, and supported in their work environment, they are more likely to experience higher levels of job satisfaction [54, 55].

The findings of this study confirm those of previous research that noted that discrimination against CALD nurses exists in healthcare organisations [11, 56], and minority nurses are at higher risk of discrimination than native or majority nurses [56]. In this study, it was found that CALD nurses may experience differential treatment compared to their colleagues, which includes fewer opportunities for professional development, lower pay and benefits, limited choice in shifts, inadequate access to education, limited chances for promotion and leadership roles, insufficient quality of mentoring, and challenges in maintaining work-life balance. In addition, there was evidence that CALD nurses feel mistreated at work by their fellow nurses, patients, and their families. The experiences of discrimination varied depending on race and ethnicity; those in the Black minority were more likely to experience discrimination and lack of support compared to other CALD nurses and were less unaware of their employers have an equal opportunity policy. Moreover, CALD nurses who were educated in low-income countries or were recruited through staffing agencies were more likely to report experiencing unequal treatment compared to their counterparts—for example, wages were found to be approximately 14% higher for CALD nurses educated in high-income countries compared to those educated in low-income countries.

Furthermore, certain healthcare workplaces and individuals may lack cultural competence, which refers to understanding and effectively working with people from diverse cultural backgrounds [57]. Without this understanding, discrimination and biases can arise, impacting CALD nurses' experiences in the workplace [58–60]. Moreover, inadequate policies, lack of diversity and inclusion initiatives, and biases in recruitment and promotion processes may perpetuate discriminatory practices [60].

A CALD nurse's linguistic competence can challenge their integration into the working environment [61]. This study reveals that communication in English emerged as a predominant factor associated with job satisfaction among nurses from non-English speaking backgrounds. Bridging programmes and language support initiatives are designed to assist CALD nurses in adapting their education and skills to meet the requirements of the new healthcare system. These programs provide language training, cultural orientation, and additional education or training to enhance their competence and enable a smooth transition into the new healthcare environment [62].

Acculturation involves learning and adopting the values, behaviours, and traditions of another group or society, it is the process by which a cultured individual adopts some customs and cultural norms of another culture. This process can happen on a group or individual personal level, for instance, when an individual moves to a new country and adopts the customs of their new cultural context [63]. To

enhance the commitment of Asian nurses, it is crucial to understand their cultural values and create a culturally competent and sensitive environment. In the context of Asian cultures, which often have collectivist values, individuals prioritise the needs and goals of the group over individual interests. This orientation can significantly influence the level of organisational commitment among Asian nurses [45, 64, 65]. The findings of this study reveal that Asian nurses with a stronger collectivist orientation demonstrate more significant organisational commitment and job satisfaction. For example, nurses born in China demonstrated a lower level of organisational commitment and acculturation. They expressed a greater desire to immigrate to other countries to practice healthcare. Organisations that employ a significant number of Asian nurses with a collectivist orientation can influence this cultural value by fostering an environment that supports teamwork, collaboration, and a sense of belonging.

Finally, the findings revealed that the factors that influence the sociocultural adjustment of CALD nurses include job satisfaction, the current work environment, and a sense of belonging in the host country. The successful adaptation to the sociocultural aspects of a new country is a crucial component of the migrant experience, thereby impacting mental health and overall psychological well-being in their professional roles [66].

5.1. Limitations and Strengths. The PRISMA 2020 checklist was completed and implemented during this systematic review process [31]. One of the limitations of this study concerns publication bias, as it only included published, peer-reviewed articles in English or Finnish, and the search did not include a search for grey literature. In addition, this review was conducted following the JBI guidelines for evidence synthesis, explicitly focusing on systematic reviews to ensure transparency in reporting the review process and findings. In addition, the JBI critical appraisal tool for analytical cross-sectional studies was utilised to assess the methodological quality of the included studies.

The synthesis of statistics in this review posed a significant challenge due to the heterogeneity observed in outcomes across the included studies. Variations in study designs, populations, interventions, and outcomes can impede the pooling of data or the formulation of definitive conclusions.

The adopted methodological choice of a systematic review may have introduced limitations due to the nonconsideration of diverse knowledge, such as policy papers that may have proved valuable to our findings [67]. However, we find that a systematic review was well suited due to the opportunity this research method offers as a systematic, unbiased approach towards providing existing research findings that may inform practice, policy, and future research [68]. Furthermore, systematic reviews are used to build an evidence base that confirms or refutes current practice [28]. In the case of this review, established evidence relating to factors associated with CALD nurse organisational integration may be used to confirm or refute current organisational integration practices.

6. Conclusion

The factors associated with integrational strategies and models developed to support the transition and adaptation of CALD nurses to the professional workforce in healthcare include sociodemographic characteristics, discrimination, social support, organisational support, workplace environment, and acculturation. The study highlights the significance of job satisfaction among CALD nurses, emphasising its impact on turnover rates and, consequently, patient care quality and safety. Factors influencing job satisfaction include supportive work environments, equal treatment, access to resources and education, and positive team culture. Furthermore, the review underscores disparities in job satisfaction among different racial and ethnic groups, with Black minority nurses often experiencing lower levels of job satisfaction. It stresses the importance of creating inclusive workplaces to enhance the job satisfaction of CALD nurses. The study also addresses discrimination against CALD nurses within healthcare organisations, noting challenges such as limited professional development opportunities, unequal pay, and mistreatment by colleagues, patients, and families. In addition, it discusses the role of cultural competence in CALD nurse integration, highlighting the importance of communication skills, language support initiatives, and understanding cultural values, particularly among Asian nurses with collectivist orientations. Finally, the review emphasises the impact of sociocultural adjustment on CALD nurses' professional roles and overall psychological well-being, stressing the importance of support mechanisms for successful adaptation.

Overall, this systematic review provides comprehensive insights into the challenges and facilitators of integrating CALD nurses into healthcare systems, offering valuable implications for policy and practice in fostering inclusive and supportive work environments. This research is valuable for identifying specific integration needs and adapting support strategies accordingly. Based on the study's outcomes, we recommend policymakers, nurse employers, and nurse leaders implement targeted interventions, engage CALD nurses in ongoing professional development, and provide language support services to improve the supportive environment. Comprehensive cultural competency training for all healthcare staff, including managers, enhances cultural competence in healthcare work environments, improving the ability to work with nurses from diverse cultural backgrounds effectively. Establishing clear guidelines to address discrimination and bias creates a supportive environment where CALD nurses feel valued and respected, facilitating their adaptation and integration into the healthcare organisation. In future research, there is a need to address the worsening global nursing shortage, which is driving a rise in international nurse migration to developed countries. Ensuring fair treatment and ethical integration is crucial for CALD nurse work satisfaction and organisational success. There is a need to involve patients through research and understand their experiences with CALD nurses, which may help better patient-CALD nurse relations and may result in positive care outcomes. With emerging technology-

enhanced healthcare as a solution for nurse human resource shortages, patients uncomfortable with international nurses may choose technology as a substitute. This raises the question of whether developed countries' healthcare institutions will invest in international nurse integration due to cost concerns. We, however, note that nurse migration is on the rise due to current and future nursing workforce shortages, and research on organisational integration of CALD nurses shows that better outcomes could be achieved if organisations were to invest and structure integration strategies within the formal structure of a healthcare organisation.

7. Relevance to Clinical Practice

Our results point out factors that associate integrational strategies and models to support the transition and adaptation of CALD nurses to the professional workforce in healthcare settings. Ensuring the integration of CALD nurses into clinical practice benefits encompass enhancing of diversity and cultural competence of the healthcare team and enabling knowledge and skills exchange with nurses who have a global health perspective prevalent in their home countries. Cultural diversity enhances patient-centered care by making patients feel more comfortable and respected when coming from diverse backgrounds themselves. Eventually, CALD nurses' integration can address workforce shortage and competence exchange among the countries. This study has a significant implication on nursing management since previous research on CALD nurse organisational integration has established that nurse leaders and managers are integral in supporting the entire workforce through equity and equality towards bettering CALD nurse integration. The findings have established factors associated with CALD nurse organisational integration; these findings impact nursing workforce practices and how a healthcare organisation may invest in developing structural strategies and models that support CALD nurse integration the best.

Data Availability

All data generated during this study are included within the article.

Additional Points

What Does This Paper Contribute to the Wider global Community? (i) Effective integration allows culturally and linguistically diverse nurses to maximise their career potential as professional nurses in their host countries. Therefore, any strategies and models developed and implemented must adopt a multidimensional approach, considering factors associated with integrating culturally and linguistically diverse nurses. (ii) A safe and supportive work environment plays a vital role in the job satisfaction and career development of culturally and linguistically diverse nurses. (iii) Black minority nurses demonstrate lower levels of job satisfaction than their White counterparts, emphasising the need to build an inclusive work environment with zero avoidance to discrimination.

Conflicts of Interest

The authors declare that they have no conflicts of interest.

Introduction. The COVID-19 pandemic has had a significant impact on healthcare professionals globally, with nurses facing diverse challenges at the forefront. Despite their resilience, nurses are experiencing emotional burdens, which have contributed to a growing intention to abandon the profession. Understanding these factors is crucial for addressing the global nursing shortage. **Methods.** A qualitative descriptive approach was utilized for this study. Nurses who were actively working during the last waves of the pandemic in Catalonia, Spain, were intentionally recruited through social media and personal contacts, and data were collected through online semistructured interviews until data saturation was reached. Data were analyzed using Braun and Clarke's thematic analysis method. **Results.** Fourteen nurses, with an average of 22.8 years of work experience, were interviewed. Thematic analysis revealed three main themes: (1) the impact of COVID-19 on health, (2) factors influencing the decision to stay, and (3) recommendations to improve crisis management. **Conclusion.** Nurses faced significant emotional impacts but demonstrated dedication and resilience. Their decision to persevere was influenced by factors such as responsibility, guilt, and economic stability. Urgent measures are necessary to provide tailored mental health support and recognize emotional challenges in crisis preparedness.

1. Introduction

The COVID-19 pandemic generated an unprecedented global health crisis, affecting millions of individuals worldwide, including healthcare professionals. At the forefront of this unexpected battle, nurses assumed a challenging role by caring not only for those impacted by COVID-19 but also playing an important part in preventing infection. In addition, nurses took on more responsibilities and learned new techniques and skills related to the novel situation at the start of the outbreak, including providing psychological support facing isolation, remote patient monitoring, PCR tests, among

others. Despite the negative effects that nurses may have faced in terms of health and job satisfaction, they bravely dealt with the health-related challenges accompanying the pandemic, especially in the areas of mental health, isolation, and physical sequelae [1, 2]. Consequently, such ongoing struggle led to emotional and psychological burdens as well as fatigue, which impacted nurses' professional and personal well-being. This may be the reason for the continuing rise in their intention to abandon the profession, which subsequently contributes to the global nursing shortage and healthcare organizations' endeavor to provide professional, high-quality, and safe care [2].

There is considerable interest in the impact of COVID-19 on the emotional and mental well-being of healthcare providers, particularly in the initial year and early waves of the pandemic. These professionals were exposed to high levels of stress, anxiety, and physical and emotional exhaustion due to the uncertain situation they found themselves in [3]. In this context, early evidence suggests that a substantial number of healthcare workers experienced mood and sleep disturbances during the initial stages of the COVID-19 outbreak [4].

Moral distress, compassion fatigue, burnout, and post-traumatic stress disorder (PTSD) have been used to describe emotional states that lead many health professionals, including nurses, to consider abandoning the profession [5]. However, it is important to note that nurses who experience unresolved stress are more susceptible to burnout [6], which highlights the interconnectedness of these emotional challenges. Moreover, nurses working on the front lines have reported experiencing fear, anxiety, stress, social isolation, depressive symptoms, uncertainty, and frustration [7], underscoring the severity and complexity of the emotional toll faced by healthcare professionals. In line with the scientific literature, these experiences impact psychological well-being and can significantly affect job satisfaction, potentially influencing one's intention to abandon the profession [8, 9].

Burnout leads to poor job satisfaction and a higher likelihood of turnover [10]. Even prior to the COVID-19 pandemic, factors such as psychological stress, job burnout, and dissatisfaction were already related to a higher turnover intention [11]. A healthy work environment has positive effects on nurses, and nursing care is positively linked with patient outcomes [12]. This context may explain why nurses' well-being and turnover intention became serious concerns for healthcare managers and decision-makers regarding the workplace due to the additional stress experienced during the COVID-19 pandemic [8].

In some cases, during the early stages of the pandemic, nurses directly caring for COVID-19 patients, especially those who felt poorly prepared and overwhelmed, exhibited a high intention to leave their job [13]. This phenomenon of turnover intention has been explored in the literature. For instance, Yu et al. [9] suggest that during the early stages of the pandemic, the intention to leave among nurses was notably lower compared to the data provided by mass media reports, suggesting a discrepancy in perceptions. On the other hand, Raso et al. [14] indicated that 11% of a sample of over 5,000 nurses expressed an intent to leave their positions, while 20% remained undecided. However, when considering leaving the profession or being undecided about their future career path, both percentages were lower at 2% and 8%, respectively. Further insight into this phenomenon is provided by Nashwan et al. [15]; whose study conducted in Qatar during the initial waves of COVID-19 compares turnover intentions before and during the pandemic, revealing significantly higher turnover intentions during the pandemic period compared to before COVID-19.

This evidence underscores the complexity of nurses' intentions to leave their positions during the pandemic and

emphasizes the importance of understanding the contextual factors that influence turnover intentions. Much of the existing literature—including studies published in 2023—relies on data collected between 2020 and 2021. It is noteworthy that during that period, the cumulative stress and professional fatigue associated with COVID-19 were still in their early stages. Consequently, these numbers may fluctuate due to prolonged exposure to the situation. The impact of the prolonged duration of the pandemic and the experiences accumulated over subsequent waves of COVID-19 in 2022 have not been as comprehensively explored in the literature to date. Hence, there is a lack of qualitative studies that specifically address this phenomenon, which are needed to deepen our understanding of healthcare professionals' experiences.

Widespread shortages of nurses on a global scale pre-dating the pandemic [12, 16], exacerbated by the emergence of COVID-19 [17], underscore the critical need to delve into the reality experienced during the later stages of the pandemic. It is crucial to delve deeper into the underlying motivations and circumstances that have contributed to the alarmingly high rates of nurses expressing an intention to abandon their nursing practice. In this investigation, we aim to study the impact of COVID-19 on motivation and emotional well-being of Spanish nurses, specifically within the context of the sixth and seventh waves of COVID-19 (Oct 2021 to Feb 2022 and May/June 2022 to Aug 2022). Identifying the underlying factors that may influence nurses to consider abandoning the profession is essential, as understanding what drives nurses' intentions to leave has significant implications for the ability of health systems to cope with future health crises. Our findings may be helpful for healthcare managers, policymakers, researchers, and educators to gain a comprehensive view of this phenomenon; the results can also be utilized to design and implement strategies to help nurses cope with stress, to motivate them, to improve their well-being, and to retain them within healthcare organizations.

2. Methods

2.1. Design. We used a descriptive qualitative method to explore nurses' perspectives on their lived experiences, focusing on their intention to leave the profession alongside the factors and motivation influencing nurses' decisions to continue working as nurses despite this initial intention. Within this framework, we delve into the motivations of nurses who express the intention to leave the field, regardless of whether they have actually left or ultimately decided to stay, in order to provide a comprehensive understanding of the "intention to leave" phenomenon. This approach aims to provide clear descriptions of personal experiences and perspectives without unnecessary complexity or ambiguity [18].

2.2. Participants. Participants were selected through purposive sampling [19], guided by a decision-making framework aimed at achieving representativeness and diversity in terms of work experience, gender, age, and geographic

location, while ensuring sample diversity among those who met the inclusion criteria. The study's inclusion criteria were to be a registered nurse who (1) had worked in the region of Catalonia, Spain, during the approximate periods of the sixth and seventh waves of the COVID-19 pandemic in this region and (2) had intention to leave the profession. This method aimed to capture a range of perspectives and experiences to enrich the analysis and interpretation. Information about the study was distributed using social media and personal contacts. Once participants contacted the principal investigator, the full details of the study were provided, and all possible doubts were dispelled in order to obtain their informed consent. Prior to each interview, participants were provided with a detailed explanation of the study and its importance, aiming to establish trust and rapport. All doubts and concerns were addressed to ensure participants felt comfortable and willing to share their experiences openly. Pseudonyms were used to ensure anonymity. The research team assured the participants that their information would be kept confidential. This was expressed openly in the informed consent form. The participants did not receive any financial incentive for their involvement. Finally, 14 nurses agreed voluntarily to participate and gave written consent to be interviewed. Even though they were informed about their freedom to withdraw from the study whenever they needed or wished to, none of them did.

3. Data Collection

We gathered data through semistructured interviews between January and March of 2023. Each interview was conducted within a 30–45 minute framework, and participants were given the flexibility to choose their preferred meeting format, with all opting for online convening. The interviews were carried out using Teams® by a researcher with broad experience conducting these types of interviews who did not have any direct relationship with the healthcare organizations where the nurses worked. A script was developed based on prior knowledge and research concerns, and the final version was created after several team meetings (see Table 1). The study's objectives guided the design of the questions, which focused on the emotional impact of subsequent waves of the pandemic, the nurses' experiences, and their reasons for intending to leave the profession, as well as the factors that influence their intention and decision.

The study participants were encouraged to share their experiences during the pandemic, including their feelings, thoughts, and personal reflections. Qualitative, descriptive studies normally use small samples [20]; however, the final sample size was determined through data saturation [21]. Data saturation is achieved when enough information has been obtained to replicate the study and when the ability to obtain additional information has been accomplished and further coding is no longer feasible [22].

3.1. Data Analysis. We performed thematic analysis following the method developed by Braun and Clarke [23] with assistance from the Atlas.tiV8 software. This analytical

approach is employed in qualitative research to address general research inquiries. The outcome of thematic analysis consists of one or more themes that shed light on individuals' encounters, perspectives, and standpoints regarding the phenomenon in question [23]. The quotes were translated into English and validated by two bilingual members of the research team (JL and CW) to ensure that the translated quotes retained not only the syntax but also the original meaning. The data analysis process began with multiple readings, where a single researcher (JL) led the effort to acquaint himself with the data content. The researcher assigned descriptive codes to identified content pieces and subsequently categorized these codes according to similarities and differences. Following this, the researcher engaged in discussions over several sessions to reach a consensus with the rest of the research team and ensure the analysis's rigor and reliability. Through this iterative process, the data was comprehensively examined and interpreted from diverse perspectives, ensuring an accurate representation of participants' experiences.

3.2. Trustworthiness. We relied on the Consolidated Criteria for Reporting Qualitative Research (COREQ) checklist [24]. Throughout the research process, we adhered to the rigorous criteria proposed by Guba and Lincoln [25]. We closely and continuously monitored the process to ensure reliability, paying attention to the accuracy of the transcripts, and comparing them with the corresponding audio recordings. In addition, we carefully read the transcripts multiple times to guarantee the fidelity of the content. To ensure the accuracy and validity of the identified categories, two experts in qualitative methodology who were not part of the research team reviewed and confirmed the analytical process and results, which had also been approved by some participants. The research team members made efforts to identify any personal assumptions or preconceptions they may have held and to separate them from the study. The principal investigator was always available for debriefing and addressing any concerns or uncertainties during the process of analyzing the data.

3.3. Ethical Considerations. The study received ethical approval from the Ethics Committee for human and animal experimentation of the Autonomous University of Barcelona. Informed consent was obtained from all participants after providing them with detailed information about the study, including its importance and the procedures for maintaining confidentiality. Pseudonyms were used to ensure anonymity, and participants were assured that their information would be kept confidential, as expressed in the informed consent form. Additional measures were taken to protect participant privacy. All collected data were stored securely and only accessible to authorized members of the research team. Identifying information was kept separate from the main dataset to further preserve anonymity. During data analysis and reporting, aggregated findings were presented to prevent the identification of individual participants. Participants did not receive any financial incentives for their involvement in the study.

TABLE 1: Semistructured interview guide.

Semistructured interview guide
<i>Introduction</i>
Thank you for participating. Can you please start by telling me a bit about yourself and your background as a nurse?
<i>Understanding the impact of COVID-19</i>
How do you currently feel?
How would you describe your mental health today?
What relationship do you think it has with COVID or the pandemic we have experienced?
How has the COVID-19 pandemic affected your work as a nurse?
Can you describe any challenges or difficulties you have faced in your role during the pandemic?
How has the pandemic impacted your mental health and well-being?
<i>Exploring intention to leave the profession</i>
I see that you answered in the previous encounter that you have considered leaving the nursing profession, particularly during the COVID-19 pandemic, can you explain more?
What factors contributed to this consideration?
Can you describe any specific instances or experiences that led to thoughts of leaving the profession?
What factors ultimately influenced your decision to stay in or leave the nursing profession?
<i>Closing</i>
Is there anything else you would like to add or discuss regarding the impact of COVID-19 on your profession and mental health?
Do you have any final thoughts or reflections you would like to share before we conclude the interview?

Ethical guidelines were strictly followed to ensure the protection of participants' rights and well-being throughout the study.

4. Results

4.1. Participant Characteristics. A total of 14 nurses, ranging in age from 27 to 61 years with an average of 22.8 years of work experience, participated in the study (see Table 2). The participant group included representation from all four Catalan provinces, with a majority of female participants. Moreover, the participants came from various professional backgrounds, which contributed to the study's broad range of perspectives.

4.2. Qualitative Results. All respondents reported considering leaving the profession at some point during the sixth and seventh waves of the COVID-19 pandemic. Thematic analysis of the data revealed three main themes: (1) the impact of COVID-19 on health; (2) factors influencing the decision to stay in the profession; and (3) recommendations to improve the management of similar situations (see Table 3).

4.3. The Impact of COVID-19 on Health. The participants reported feeling tired both physically and emotionally. The COVID-19 pandemic revealed the chronically precarious situation of the profession and the healthcare system in general. Nurses were exposed to exhaustive levels of pressure to care for patients as well as emotional fatigue that endangered their health and continuity in the field.

I'm not sure if it was COVID-19 or because of COVID-19 that we realized how poorly we were doing. The arrival of COVID-19 made it clear to us. We had been at a low point for so long that I can't even recall how many years it's been. While COVID-19 is now under control, we remain at a low point, with exhausted, demotivated, and irritable people. The things we went through during the first waves [of the pandemic] are still present, and I have vivid memories of them. I've witnessed individuals pass away [before], but it wasn't simply the act of dying. It was the way in which it all unfolded—the disorder, the terror. To persevere through the initial and second instances was quite the feat, but these more recent waves have been something else entirely. Chaos continues to reign every single day. If—and when—another virus like COVID-19 arises, brace yourselves, because I truly don't think half of us could endure it. (P4)

This reported lingering sense of professional uncertainty, combined with fatigue from the COVID-19 pandemic, led to a sense of disillusionment with the healthcare system, its management model, and nursing practice. Although all participants affirmed that the field has provided them with deep satisfaction, many of them indicated that nowadays, if given the choice, they would pursue a different career path because nursing has changed significantly and does not meet their expectations any longer.

I would choose a different career, like art history or archaeology, if I could go back to high school. I wouldn't pick anything related to health. (P3)

I like being a nurse, but not this [kind of] nurse. (P8)

At work, I did notice the fatigue, and I also got a little burned out. I have come to question my work. (P5)

After five previous waves of COVID-19, study participants faced the sixth and seventh waves with a significant toll taken regarding their physical and emotional health. Episodes of anxiety, depression, insomnia, irritability, and post-traumatic stress are particularly prominent at varying levels of severity. The symptoms of these conditions did not emerge in an acute

situation stabilized and there was no evidence of any change in the management of their precarious working conditions, in addition to a marked shortage of nurses, the participants began to take sick leave and had thoughts of abandoning the profession. The participants admitted that the pressure of the situation did not allow them to leave because they felt guilty. Quitting their jobs meant burdening their colleagues with more work since the possibility of finding replacements was practically nil. Therefore, on numerous occasions, they faced the dilemma of wanting to feel good themselves or sacrificing their well-being to make others feel good.

In January 2021, I began taking medication for anxiety prescribed by my doctor so I could continue going to work. It was either that or take time off due to sickness, but I felt too unwell to do so. I experienced the common feeling of guilt because I believed my colleagues needed me, and I couldn't abandon them. (P12)

However, the nurses acknowledged that to leave the field implies accepting defeat, and this is the chief reason why they remain in the profession, which they initially chose with enthusiasm and which has brought them happiness for many years despite the challenges. In addition, quitting nursing practice would mean losing the few labor rights and privileges they had obtained through their careers (particularly in terms of working hours, facility, and acquired seniority). The nurses were realistic and admitted that they have economic needs they are currently able to meet. They expressed uncertainty about their ability to meet those needs if they were to switch to another profession and start from scratch. As a result, despite their complaints and general dissatisfaction with the situation, they said they prefer to tolerate it rather than face financial instability or difficulties in terms of family reconciliation.

I cannot give up. I still have many years of work ahead of me. It's my job, and I love it. I want more than just applause—I want real recognition. What I've gone through should serve a purpose beyond just keeping me going. (P1)

Then I considered the possibility of moving elsewhere and not being able to balance my work and family life. However, I decided against it because I currently have a schedule that allows me to be with my children and assist them as needed, even if I work on some weekends. If I move to another center, I may lose this routine and stability, which I prefer to maintain (P7).

4.5. Recommendations for Improving the Management of Similar Situations. As for feeling professional fatigue and disillusionment, the nurses felt they were ignored during the pandemic, both at the political level and at the middle/higher levels in their workplaces. One of the participants referred to feeling “*ignored*” and “*belittled*.” Many of the participants expressed this view, revealing a pervasive sense of

disappointment. The nurses acknowledged the exceptional nature of the situation but were highly critical of the management of access to protective materials, work shifts, breaks, and other measures, which were adopted without considering their input. As a result, the management of the situation adversely affected their physical and mental health, leading to dissatisfaction with the profession.

Maybe they're not listening as much anymore. The mid-level managers seem busy, and it seems like the top executives are on their own. They believe we can handle everything, but we can't. Things used to be done differently. Things used to be done a certain way, but we were abruptly informed that they would now be done differently. They didn't directly ask us [for our input], as if we weren't important or weren't being considered. (P7)

We've been experiencing this throughout the pandemic. The authorities take care of themselves, and we have to tolerate whatever they decide, without any consideration for our opinions. We have to accept our situation and move forward. (P9)

I'm okay, but my voice trembles when you ask how I feel. We always say “fine” because there's no time to talk and we've been through too much to complain. But it upsets me and makes me angry that nobody cares how we really are. They applaud us but don't listen to us. (P8)

The participants recognized the need to alter their approach to the profession, including their understanding, management, and even their attitude towards it. They realized the importance of adopting a model of emotional self-management centered on self-compassion and assertiveness over absolute dedication to others. This means placing the person and the professional in the foreground without affecting the quality of care, learning to listen to signs observed in the body, and knowing how to identify when it is necessary to pause without feeling guilty.

We should prioritize carving out more leisure time to pursue personal growth and activities outside of the healthcare field. (P3)

I decided I needed a break and some rest. I [focused on] myself and didn't want to be all over the place anymore. I quit one job and now I have more time for myself. I do acupuncture and yoga to take care of myself. If we only focus on others, we'll spiral downward. Who takes care of you? (P9)

The nurses invited the managers to become more involved with the emotional needs of their teams and to truly assess whether the care facility where they were located was the right one for them. They demanded that vacancies be filled, taking into account the experiences of the

professionals as well as their personal preferences, thus facilitating a work-life balance.

Nursing managers should consider their staff's opinions by asking them if they are content with their current location or if they would prefer a change. This simple gesture can improve employee satisfaction and motivation at work. (P2)

5. Discussion

Our findings indicate that continuous exposure to COVID-19 impacted nurses' self-perceived health and well-being as well as their intention to leave the field. The participants expressed feelings of being ignored, enduring fatigue, and dealing with mental health challenges such as emotional instability, irritability, insomnia, and depression. Our results align with a growing body of evidence that highlights a surge in mental health problems among healthcare professionals during the COVID-19 pandemic [3, 26]. For instance, intensive care nurses experienced helplessness, exhaustion, and mental health issues; moreover, a significant percentage of primary healthcare nurses exhibited symptoms of depression, anxiety, and stress, which they attributed to the pandemic [27], and Martin-Rodriguez et al. [28] reported a significant prevalence of depression, anxiety, insomnia, and distress among nurses, particularly those working in COVID-19 units and nursing homes, who appeared to be particularly affected. Providing a broader context, a systematic review encompassing studies from 2020–2021 showed a high prevalence of moderate-to-severe symptoms of anxiety, depression, PTSD, and insomnia among nurses [3]. These findings collectively underscore the ubiquitous nature of mental health challenges among healthcare professionals during the COVID-19 pandemic.

The nurses felt abandoned by their healthcare institutions. They felt unsupported, especially during the early stages of the pandemic when uncertainty and fear were multiplying. The sense of abandonment expressed by our participants can be linked to the sense of being betrayed found in the literature discussing the concept of institutional betrayal among healthcare workers [29]. In this study, healthcare workers described frustration when their institutions did not prioritize their safety, and they believed that they had received inadequate compensation. Feelings of having been betrayed by their institutions were associated with increased burnout and a stronger intent to quit their jobs [29]. This highlights the critical need for healthcare organizations to foster a supportive and trustworthy environment for their staff, particularly during times of heightened uncertainty, such as during crises.

The present study indicates that nurses experienced significant changes in their working conditions, and they felt disillusioned at the professional level as well as personally transformed. These results align with prior research that has identified similar experiences of professional grief [30], turmoil, and personal transformation [31]. In essence, the present study suggests that nurses are deeply disappointed with the management system and with what the profession

has become. Their profession is no longer recognized, which makes them think they would not choose nursing if they could go back in time and choose a different career. The findings underscore the disillusionment experienced by nurses with the current state of their profession, highlighting the urgent need for systemic changes to address their concerns and restore recognition and value to the nursing profession.

It is important to acknowledge the differences between our findings and those of prior research, where some nurses found renewed purpose and meaning in their roles during the pandemic [32, 33]. These differences may be attributed to the evolving nature of the pandemic, the varying experiences of healthcare professionals at different points in time, and our specific focus on individuals who have contemplated abandoning the profession. The differences in results underline the complexity of nurses' experiences during a crisis as well as the need for further research to better understand the shifting dynamics of nurses' professional lives. However, our findings partly align with those of Litzzen-Brown et al. [32] as their participants described how the circumstances of the pandemic led them to provide suboptimal care. The consequences of this environment and the barriers to providing optimal nursing care had significant ramifications for the nurses, leading to constant feelings of frustration and being at a loss.

Finally, evidence suggests that a challenging work environment, a lack of support, emotional distress, and disappointment regarding the reality of the field were factors that reinforced nurses' motivation to leave the field [34]. This reality points to the urgent need for effective mechanisms to provide mental health support within healthcare organizations, as emphasized by our participants' suggestions for prioritizing personal well-being in future crisis management in order to foster retention.

We identified a number of factors that dissuaded nurses from abandoning the profession such as a sense of responsibility, feelings of guilt, pressure from management teams, economic considerations, and a desire to preserve working conditions. All these factors played pivotal roles in their decisions. In this regard, various factors influencing nurses' intention to stay or leave the field have been highlighted in the literature [9], including education level, mastery and expertise, perceived support, nurse-manager communication, stress levels, and family-related factors such as marital status or having children. These factors emphasize the individualized nature of nurses' decisions regarding their professional future. The interplay between individual motivations and organizational influences is essential in fully addressing nurses' intentions to remain in or leave the profession.

Several studies have examined the pandemic's impact on retention and turnover among nurses. In the present study, economic stability and favorable working conditions influenced nurses' decisions to stay in their roles. Squires [31] suggested that financial incentives, often linked to economic stability, are a driving force behind attrition rates. This highlights the undeniable connection between financial well-being and a nurse's decision to stay in the field,

reinforcing the significance of economic considerations in nurses' career choices. It is important to note that while these factors resonated with our participants' experiences, there is also a degree of variability in how different nurses respond to these pressures. A study among senior nurses in Ireland showed that despite the adverse health impacts, some nurses responded positively to the pandemic, while others chose to retire early [35]. This variability demonstrates the multifaceted nature of nurses' decisions in the face of adversity.

Bahlman-van Ooijen's [34] qualitative systematic review indicates that nurses' reasons for quitting nursing practice include numerous difficulties, including a challenging work environment, emotional distress, disappointment about the reality of nursing, and a culture of hierarchy and discrimination. These findings offer valuable insights into areas where targeted interventions and improvements can be implemented. Furthermore, a longitudinal study conducted across two phases identified emotional states such as moral distress, compassion fatigue, burnout, and PTSD among nurses, which significantly influenced their thoughts of abandoning the profession [5]. The present study emphasizes the need to create a psychologically safe workplace to support retention among nurses. Additionally, frontline nurses experiencing compassion fatigue are at risk of lower job satisfaction and higher turnover intention [36].

In a broader context, the quality of the work environment significantly impacts nurses' risk of burnout and intention to leave the profession, with better work environments being associated with lower risks [37]. This aligns with our findings regarding the importance of preserving favorable working conditions to prevent job abandonment.

In this study, the nurses described the pivotal role of leadership, especially healthcare management, in nurturing the well-being of nurses during crises. Savage et al. [38] underscored the idea that healthcare leadership has the potential to function as both an asset and a barrier to organizational performance. Many participants described how leadership was unsure about how to provide structure and organization during the pandemic. Subsequently, nurses experienced a significant lack of support from leadership staff, such as their managers, who either were unavailable or left their positions. This observation is consistent with prior research highlighting the significance of effective leadership during challenging times [39]. Positive and supportive leadership positively affects nurses' commitment to the organization, leading to increased job satisfaction, productivity, retention, patient safety, and an overall safe climate [40]. Fowler and Robbins [41] emphasized the indispensable role of nursing leaders in enhancing efficiency, stressing the need for these leaders to exhibit both informational and motivational qualities, especially during healthcare challenges and crises. The participants' input demonstrates the critical need for strong, supportive leadership structures within healthcare organizations to mitigate the impact of crises on healthcare workers.

Moreover, the participants stressed the importance of personal growth and self-care as integral components of crisis management. This perspective resonates with the

broader literature on resilience among nursing professionals, which emphasizes personal growth as a key element of their ability to navigate and overcome challenges [42]. The participants' insights suggest that the promotion of personal growth and self-care strategies should be integrated into crisis management plans to help healthcare professionals cope with the emotional challenges they may face. Practical aspects of crisis management were also underlined by nurses participating in the present study. Ball [43] found that nurses advocated for better personal protective equipment and support for the workforce. This pragmatic feedback indicates the importance of addressing tangible concerns to ensure the safety and well-being of healthcare workers during crises.

Finally, this study shows how nurses prioritize personal their well-being. Calkins [44], who identified feelings of inadequacy and exhaustion among intensive care nurses, further highlighted the urgent need for healthcare organizations to develop strategies to mitigate burnout and provide comprehensive support to their staff. The importance of peer support and an encouraging team culture in helping nurses cope with crises has also been emphasized in the literature [45], thus demonstrating the significance of fostering positive interpersonal relationships among healthcare professionals to enhance their resilience during challenging times. In line with this, Squellati and Zangaro [6] stressed the collaborative nature of coping with the demands of the healthcare profession, underlining the need for nurses to work together to support each other and their leaders in mitigating the situation and reducing burnout.

6. Limitations

This study has some limitations. The sampling method ensured the appropriateness of the participant profile in relation to the study's objectives. However, the sample is represented only by some nursing backgrounds and specific clinical settings. Moreover, the nurses participated voluntarily. Consequently, other potential options that could be explored in future studies were left out. This also means that the experiences of nurses who did not express interest in participating may have been overlooked due to challenges associated with their unease with the topic at hand. Nonetheless, the wide range of profiles and the repetition of data ensured their reliability and dependability. Additionally, the data align with the socioeconomic context of the specific context, precluding the possibility of extensive generalization. Nevertheless, we postulate that various outcomes could be applicable in similar populations of healthcare workers worldwide. Finally, there may have been some information bias due to the sensitive nature of the subject matter. Nevertheless, we took measures to reduce this and establish a safe environment of confidentiality and nonjudgment for the interviewees.

7. Future Research

For future research, conducting in-depth studies that focus on nurses who have left the profession could provide

valuable insights into their experiences and reasons for departure. Understanding these factors in greater detail can inform targeted interventions and support strategies aimed at retaining healthcare professionals within the workforce.

Implementing action research methodologies could be beneficial in assessing the effectiveness of interventions designed to address nurses' concerns and improve retention rates. Action research principles, such as collaboration with stakeholders and iterative cycles of planning, action, and reflection, can actively involve nurses in the process of identifying and implementing solutions. This approach enables real-time adjustments based on feedback from participants, promoting a sense of ownership and engagement among healthcare professionals.

Additionally, taking into account the diverse backgrounds and experiences of nurses could improve the effectiveness of interventions. Customizing strategies to accommodate different needs and perspectives within the nursing workforce can result in more targeted and impactful solutions. By integrating insights from in-depth studies of nurses in this situation with action research methodologies, researchers can develop evidence-based strategies to address workforce challenges and enhance the sustainability of the nursing profession.

8. Conclusions

The emotional impact of the pandemic on the interviewed nurses was profound as they struggled with feelings of being overlooked, exhaustion, and mental health challenges. Despite the immense obstacles they faced, they demonstrated dedication to their field and professional commitment. Factors such as a sense of responsibility, guilt, and the importance of economic stability played pivotal roles in their decision to persevere. This resilience highlights the interconnections among personal motivation, organizational support, and economic stability in shaping career decisions during times of crisis.

There is an urgent need for comprehensive programs offering mental health support that are tailored to the unique demands of nursing. Recognizing and addressing emotional challenges must become a cornerstone of future crisis preparedness and response efforts. Apart from designing strategies to cope specifically with the effects of the COVID-19 pandemic on nurses, this study suggests the need for managers and decision-makers to propose sustainable actions that could overcome potentially similar situations. In addition, nurses' working conditions should be reviewed so that they can be retained and kept healthy, thereby avoiding situations of fatigue, stress, the intention to leave, and low motivation. Such circumstances have led to a worldwide nursing shortage and have hampered upward mobility to workplaces with better conditions.

Finally, policies and programs should be implemented at the management level that prioritize nurses' mental well-being and recognize their invaluable contributions. This multidimensional approach should include mental health support, leadership development, personal growth, and a culture of appreciation within healthcare organizations. By

investing in nurses' well-being, we not only honor their dedication but also strengthen their resilience, ensuring that they can continue to deliver high-quality care during times of adversity.

Data Availability

The narrative data used to support the findings of this study have not been made available because of ethical reasons.

Additional Points

Statement of Clinical Relevance. This study highlights the emotional impact of the COVID-19 pandemic on nurses and identifies critical factors that influence their intention to abandon the profession. Healthcare organizations can improve the well-being of their nursing staff, reduce turnover intentions, and ensure a resilient and dedicated workforce capable of delivering high-quality care, especially in times of crisis, by addressing these issues. Recognizing these challenges is crucial for healthcare administrators and policy-makers to implement targeted strategies for improving working conditions. Prioritizing mental well-being policies and fostering a culture of appreciation are essential for sustaining nursing excellence during adversity.

Disclosure

The research did not receive specific funding but was performed as part of the employment of the authors at Universidad Aut3noma de Barcelona, Grup de Recerca Infermera en Vulnerabilitat i Salut (GRIVIS), Nursing Department, Faculty of Medicine. Except Manuel Lillo-Crespo who did collaborating with our team without payment.

Conflicts of Interest

The authors declare that they have no conflicts of interest.

Acknowledgments

The authors express our gratitude to the nurses who participated in our study and shared their experiences. The authors also extend our thanks to the team led by Cristina Garcia-Vivar and Leticia San Martin-Rodriguez, professors from the University of Navarra, for their invaluable and inspirational advice during the preparation of this study. Open access funding was enabled and organized by CRUE-CSUC 2024.

Background. Nurses face significant challenges as they attempt to manage an increasing number of complex responsibilities within limited time frames. This article explores the factors contributing to time-wasting behaviors among nurses in Palestine and emphasizes the significance of effective time-management skills in nursing practice. **Methods.** Surveys were collected from a total of 714 nurses working in multiple healthcare facilities located in the north of the West Bank, Palestine. An 11-item time-wasting scale was developed and validated. Factors influencing time-wasting behaviors among nurses were then investigated using multiple linear regression in SPSS version 25. **Results.** Attending time management courses significantly reduced time-wasting behaviors. Additionally, factors such as age, gender, and educational level did not appear to correlate with time-wasting behaviors. However, workplace, type of organization, and attendance of time management courses did impact nurses' time management skills. **Conclusion.** This article underscores the importance of time management skills in nursing practice. Inefficient time management can have detrimental effects on patient care and nursing outcomes. To mitigate these challenges, healthcare institutions and nursing education programs should prioritize time management training for nurses.

1. Introduction

Nurses face ongoing challenges as they try to handle a growing number of complex tasks and demanding work conditions within the constraints of limited time [1]. In a mixed-methods study conducted in Palestine, [2], a nurse captured the challenges they encounter while endeavoring to address the requirements of all their patients: "You cannot give quality when you are overwhelmed with quantity. When I have 15 patients on a ward to take care of on a night shift, I barely have time to distribute the medications, leaving little time to care for patients' other needs." According to Saintsing et al. [3], nurses indicated that time limitations constrained their capacity to conduct thorough patient assessments. Around 80% of entry-level nurses acknowledged making errors due to time pressure. Managing time efficiently and avoiding time-wasting activities are therefore essential in the nursing work environment. The lack of time management and organizational skills was also related to inequities in health service provision and distribution [4].

Causes of time-wasting behaviors among nurses include a lack of effective time management skills. This includes not setting short- and long-term goals, failing to organize tasks, engaging in activities that waste time, and lacking knowledge and experience in setting priorities [5, 6].

Consequences of time-wasting behaviors include ineffective work performance, decreased productivity, and the potential for missing essential nursing care tasks [5]. Nurses who wasted their time and energy on social media and low-priority tasks were found to significantly lower their work performance [7]. Not knowing how to set priorities by giving equal attention to major and minor problems can have dire consequences on patients' health and overall nursing outcomes [8].

Numerous studies have consistently demonstrated a detrimental impact of ineffective time management on job performance [9, 10]. Tang and Vandenberghe [11] explained that demands that exceed an individual's available resources contribute to a decline in overall work performance and well-being. Others found that work overload negatively

affects performance through increasing stress [10]. A cross-sectional study from Brazil revealed that work-related stresses had the greatest negative impact on job performance while social networks and job autonomy had the greatest positive impact [12].

A study by Knezevic et al. [13] investigated the effects of time management skills on job satisfaction for nurses. The study found that poor time management skills were significantly associated with lower job satisfaction levels among nurses. In a related study, Ozkan & Timbil [14] found that nurses with poor time management skills made more medication errors and missed nursing care activities more frequently than those with good time management skills. The authors recommended that time management training should be included in nursing education to improve patient safety and quality of care.

Similarly, a study by Cleland Woods et al. [15] found that poor time management skills were associated with higher levels of job-related stress among nurses. The authors recommended incorporating time management training into workplace wellness programs to help nurses manage their time more effectively and reduce job-related stress. In conclusion, poor time management skills can have negative effects on nurses' capacity to provide optimal patient care. It is, therefore, essential that time management skills are included as a critical component of nursing education and workplace wellness programs.

Numerous studies, including those conducted by Hamzehkola and Naderi [16], Higazee et al. [17], Ebrahim et al. [18], and Elsbahy et al. [19], have presented sound evidence that time management interventions can enhance the organizational skills of nurses, mitigate work-related stress levels, and ultimately elevate the overall quality of their work. A time management educational program for head nurses in Iran assessed improvements in five essential time management skills (setting goals, setting priorities, time mechanics, time control, and organizing time). The results showed dramatic improvements in these basic skills after the educational intervention [20].

Another quasi-experimental experiment of 60 nurses from all hospital wards in Tehran examined the psychological and social impacts of a one-day educational workshop on strategies to improve time management and avoid wasting nursing time [16]. A pretest was followed by a posttest one month after the workshop. Results showed significant improvements in psychological well-being and trust among staff.

Setting priorities has been defined as the action of assigning precedence in rank with regard to the importance or time for some activities over others [8]. In addition to delaying activities of less importance, prioritization can also eliminate unnecessary tasks which allow nurses to allocate more precious time for patients [16]. These findings underscore the importance of time management skills for nurses. Prioritizing tasks and activities are crucial aspects of time management skills.

It has been noted that new nurses struggle with managing their time and that their abilities to prioritize tasks and minimize time-wasting activities improve with experience [21].

The degree to which this relationship is a function of experience, age, education, or other variables that evolve with time has not been extensively investigated in previous research [22]. Many studies show that time-wasting activities decrease with age, education, experience, and attending time-management courses. Most of the previous research, however, did not adjust for confounding effects in multivariate analyses [23]. The current study aims at exploring the relationships between these background variables and time-wasting behaviors in multivariate models to distinguish the most important factors contributing to time-wasting behaviors.

1.1. Principles of Setting Priorities. The fundamental question is how can nurses determine the priority, importance, and urgency of the multitude of tasks they are tasked with? Several time management theories and models can help nurses in managing their time and minimizing time-wasting activities. The items used in the time-wasting scale of this study such as appreciating planning, distinguishing important tasks, and understanding time-wasting activities reflect those principles. Those principles include

- (1) The Pareto 80/20 rule notes that 80% of outcomes result from 20% of efforts [24]. This principle calls for identifying and focusing on the most impactful tasks, i.e., the ones that yield the highest returns. The 80/20 rule therefore prioritizes the 20% of tasks that produce the best results.
- (2) The two-minute rule recommends completing small tasks (e.g., those requiring 2 minutes or less) first before embarking on tasks that are complicated or require long durations [25]. This rule helps minimize the accumulation of small tasks and fosters a sense of progress.
- (3) The effort impact matrix, also known as the PICK Chart, prioritizes tasks based on impact and effort [26]. The impact can be assessed based on financial gain, patient satisfaction, or health improvement. The impact or yield of a task ranges from low to high.
- (4) The ABC method involves categorizing tasks based on their priority and then completing the highest priority tasks while less urgent tasks can be delayed or delegated [27].
- (5) Eisenhower matrix categorizes tasks based on their urgency and importance into four quadrants: (a) urgent and important, (b) important but not urgent, (c) urgent but not important, and (d) not urgent and not important. The model helps prioritize tasks and focus on the most critical ones.

Nursing time management skills are essential for delivering efficient and effective patient care. Poor time management skills can lead to decreased patient satisfaction, inefficient use of resources, and ultimately compromised patient care [14]. Therefore, this study aimed to investigate sociodemographic and institution-level factors associated with time-wasting behaviors among nurses in Palestine. Specifically, the research questions were whether time-

wasting behaviors vary by nurses' age, gender, place of residence, and educational levels. Of interest were the effects of institutional-level factors such as type of healthcare institution (public versus private), facility size (hospital versus clinic), and teaching status (teaching versus nonteaching institutions) on time-wasting activities. The impact of attending a time-management course on time-wasting behaviors was also investigated.

2. Methods

The surveys were collected in the period between March and August 2019 from 714 nurses working in 17 hospitals and multiple primary health care clinics in the North of the West Bank of Palestine. Approval was obtained from the Palestinian Ministry of Health. The researcher contacted the nursing directors of each hospital and primary healthcare center, inquiring about the number of nurses employed within their respective organizations. Subsequently, the researcher prepared questionnaires based on the gathered information, met with each nursing director in person, delivered the questionnaires, and explained the data collection process, including its content, objectives, and the process of obtaining consent.

The nursing directors were then tasked with distributing the questionnaires to all nurses in their organizations and collecting the completed questionnaires within a week. The researcher personally collected the completed questionnaires from the nursing directors. All nurses completed the questionnaires except those who were sick or on leave.

Inclusion criteria: all male and female staff and practical nurses who were available at the time of the data collection. Exclusion criteria: nurses who were on a sabbatical leave, a sick leave, nurse volunteers, and internship student nurses. The entire process was completed within a span of six months, and the researcher, along with the assistance of two experienced data entry personnel, entered the data into SPSS version 25. The collected data were analyzed using *t*-tests and ANOVA. To account for confounding effects, multivariate linear regression was employed.

2.1. Study Instrument. The study examined various socio-demographic variables including gender, age, residence, educational level, and years of experience. Time-wasting behaviors were evaluated using an 11-item scale developed based on prior research [28]. This scale measures different aspects of time-wasting behaviors, such as excessive grooming, poor planning, failing to distinguish between important and unimportant tasks, underestimating task completion time, excessive use of social media, and excessive socialization. Responses were recorded on a 5-point scale ranging from "never = 1" to "always = 5" and a summative score was computed. Scores could range from a minimum of 11 to a maximum of 55, with higher scores indicating more frequent engagement in time-wasting activities.

The face and content validity of the study were ensured through consultations with 10 experts in nursing and time management. These experts were briefed on the study's

objectives and the construct of the scale. They were then asked to assess whether the items clearly and effectively measured their intended concepts (face validity). Additionally, the experts provided feedback on the relevance of the items and their representation of the content domains within the intended construct.

The author carefully analyzed the feedback received from the experts and made necessary adjustments to the wording and number of items. Subsequently, the revised questionnaire was pilot-tested with a group of 5 staff nurses. Construct validity was evaluated through factor analysis, and reliability was assessed using Cronbach's alpha.

3. Results

Cronbach's alpha of the entire sample was 0.862, indicating good internal consistency. Factor analysis identified three distinct factors, as detailed in Table 1. The Kaiser–Meyer–Olkin (KMO) measure of sampling adequacy was 0.845, indicating strong partial correlations among the variables and justifying the use of factor analysis. Bartlett's test of sphericity returned a *p* value of less than 0.001, which rejects the null hypothesis that the variables are unrelated. This indicates that the correlation matrix is not an identity matrix, affirming the appropriateness of factor analysis. None of the items had a commonality value above 0.4, indicating the appropriateness of factor analysis for exploring the data. Overall, the three-factor structure accounted for a substantial 76.77% of the variance in the nursing time management scale.

The divergent validity of the scale was assessed by correlating it with another scale which is theoretically intended to measure good time management behaviors among nurses. The time nursing wasting scale correlated negatively with the nursing time managements scale (NTMS), correlation coefficient = -0.162 , $p < 0.001$. The NTMS is a scale that measures positive time management skills among nurses such as planning, goal setting, and coordination of activity (Table 1).

The factor loadings, means, and standard deviations for each item within the time-wasting scale are displayed in Table 2. Higher mean values indicate more frequent engagement in time-wasting behaviors among the participants. Among the various behaviors, grooming appeared to be the least time-consuming activity, with a mean score of 2.14. In contrast, work interruptions, such as being overly accessible, ranked as the most significant time-wasting factor, with a mean score of 3.15. Following closely were behaviors like not having specific time to respond to emails and phone calls (mean of 3.03) and continuously checking emails and other communication media (mean of 2.83).

The factor analysis unveiled a three-factor model, categorizing time-wasting behaviors into three dimensions:

- (1) Inability to plan and organize tasks
- (2) Improper use of technology and social media
- (3) Excessive socialization

Table 3 shows the frequencies and means of the time-wasting scores by background variables. Of the 714

The bold values are statistically significant. Note. * $p < 0.05$; ** $p < 0.01$; *** $p < 0.001$.

participants, 34.8% were male and 65.0% were female. The mean time-wasting score for male participants was 28.02, and for female participants, it was 27.38, $p = 0.223$. The average time-wasting score of nurses over the age of 35 is higher than younger age groups, $p < 0.001$. The mean time-wasting score was highest for participants living in the camp (29.25) and lowest for those living in the city (27.00).

Regarding workplace, the table shows that the mean time-wasting score was significantly higher for participants working in a hospital (28.53) compared to those working in a patient community clinic (25.17) ($P < 0.001$). For this type of organization, the mean time-wasting score was significantly higher for participants working in a private organization (31.53) compared to those working in a government organization (26.31) ($P < 0.001$).

Regarding the current job position, the table shows that 631 participants (88.3%) were nurses, while 82 participants (11.5%) were nurse supervisors. The mean time-wasting score was similar across the two job positions, with no statistically significant difference ($P = 0.342$). Participants who worked in teaching hospitals/clinics had a lower mean time-wasting score (26.59) than those who did not work in teaching hospitals/clinics (28.88), and those who attended a time management course had a slightly lower mean time-wasting score (27.00) than those who did not attend a time management course (28.44).

The multivariate linear regression in Table 4 shows no significant relationship between time wasting and gender, age, place of residence, educational level, and job experience. On the other hand, place of work emerged as a significant predictor of the time-wasting score when other background variables were considered. Individuals working in community clinics have lower time-wasting average scores compared to those working in hospitals ($B = -3.2$, $p < 0.001$).

The type of organization was also a significant predictor of time management skills. Individuals working in private organizations engaged in more time-wasting activities compared to those working in government organizations ($B = 4.09$, $p < 0.001$).

Nurses in nonteaching hospitals are more likely to engage in time-wasting activities than nurses in teaching hospitals ($B = 2.63$, $p < 0.001$). Nurses who had not attended a time management course obtained a higher score on the time-wasting scale compared to nurses who had attended a time management course ($B = 3.11$, $p < 0.01$).

4. Discussion

This research sought to examine the predictors of time-wasting behaviors among nurses. The results indicate that time-wasting behaviors are influenced by individual-level and organizational-level factors. The finding that attending a time management course is effective in reducing time-wasting activities and improving time management skills corroborates numerous previous studies that have provided evidence for the positive impact of time management training [19, 22, 29–31].

Prior studies have demonstrated that time-wasting activities decrease with age [22]. In the current study, older age

was associated with lower time-wasting scores in the bivariate analysis, but this association did not hold in the multivariate analysis, most likely due to adjustments for confounding variables such as seniority or job experience. Similarly, job experience was associated with lower time-wasting scores in the bivariate analysis, but this relationship did not persist in the multivariate analysis. This finding contradicts previous research, which found significant correlations between years of experience and improved time management skills [23]. Educational level, however, was not associated with time-wasting behavior in this study. This result aligns with findings from a study in Bangladesh that failed to establish a relationship between educational level and time management skills [32]. In contrast, a study in Iran found significant positive correlations between time management skills and age, education, job experience, and managerial experience, probably because this study did not adjust for potential confounding effects [16].

Organizational types, such as hospital vs. community clinic or government vs. private, were strongly statistically related to time-wasting scores in this study. This suggests that organizational-level factors could influence time-management behaviors. Elsayed et al. [23] reported that organizational factors, such as understaffing, work overload due to a large number of visitors, and the absence of clear management plans, strongly influence employees' time management behaviors. Others have found that poor organizational and policy factors, such as frequent staff meetings, inefficient and unclear communications, and excessive administrative work, such as writing attendance records or tasks unrelated to their specialty, can result in significant time wastage among employees [33].

Time-wasting activities, as reported by nurses in this and previous studies, include spending too much time on low-priority tasks; treating everything as urgent; inability to say "no" to extra work; and excessive interruptions by people and colleagues [34]. Meetings that are ineffective, with no clear purpose, agenda, or follow-ups are a waste of time as well as arriving at meetings late. Other time-wasters include excessive socializing, phone calls, and phone interruptions; inefficient and unclear communications with patients and colleagues; insufficiently detailed policies and procedures; reluctance to delegate tasks; and an overload of paperwork [34].

Not knowing how to prioritize, plan, and handle interruptions can lead to increased errors and work inefficiencies [35, 36]. The findings from this study concur with previous research, which shows the inability of nurses to say "no" as one of the most important factors negatively influencing nurses' workflow [19, 35]. It is known that in Arab culture, saying "no" or "I do not know" is not commonly used, probably because such terms are thought of as impolite. Nevertheless, nurses should learn to refuse additional tasks that they cannot perform or tasks that interrupt their workflow. Other major time-wasters mentioned in previous research include not knowing how to delegate. Figure 1 illustrates a theoretical framework of the types, causes, and consequences of time wasting in the nursing profession. The figure summarizes the findings from this article and previous studies.

4.1. *Limitations.* While this study was carried out on a representative sample within the northern regions of Palestine, it is important to note that generalizing the

findings to other contexts may not be fully established. To strengthen the generalizability of the findings, it is necessary to conduct further research in various other contexts.

Moreover, as a cross-sectional study, causal inferences are constrained. Nevertheless, one strength of this study lies in its high sample size, addressing the constraints associated with smaller sample sizes in earlier research.

Although having the nursing directors distribute and collect the surveys has increased response rates and motivation to complete the questionnaires with precision, it cannot be ruled out that some respondents may have been unduly influenced to participate despite the fact that it was explained to them that participation is voluntary.

5. Conclusions

According to the results of this research, providing time management courses to nurses can be an effective strategy to reduce time waste and improve work quality. However, in addition to providing time management courses, hospitals and clinics should also consider implementing organizational policies and strategies to reduce time-wasting activities.

5.1. Recommendations. Hospitals and clinics should conduct regular time management courses for their employees, with an emphasis on providing practical instructions and exercises on how to avoid and eliminate time-wasting activities such as interruptions, distractions, and procrastinations. In addition, organizations should design policies that minimize time-wasting activities, such as requiring excessive reporting, vague communications, and unnecessary meetings. Such policies should be clearly communicated to all employees.

In addition to time management courses, organizations should also provide their employees with the necessary tools and resources to manage their time effectively, such as time-tracking software or prioritization frameworks. By following these recommendations, hospitals and clinics can create a more productive work environment and improve the quality of care they provide to their patients.

Data Availability

The dataset examined in the present study can be obtained from the corresponding author upon a reasonable request.

Ethical Approval

Nurses were informed that participation in the questionnaire is optional and that no adverse consequences will arise from choosing not to participate. They were assured that their names would not be gathered and data confidentiality would be maintained by securely storing the questionnaires solely for research purposes.

Consent

Informed consent was acquired from all participants, including staff nurses and nursing directors. Ethical approval to conduct this study was obtained from the IRB of the American Arab University, Palestine IRB #13.P.E/22.

Conflicts of Interest

The author declares that there are no conflicts of interest.

Authors' Contributions

RZ completed this article.

Acknowledgments

The author expresses gratitude to the nursing directors who assisted in collecting the data, without whom this research would not have been feasible. Special thanks are also extended to the participating nurses who contributed to the survey. This research was completed by the author herself without external funds.

Aims. To identify the factors influencing hospital nurses' workplace bullying experiences (victim and perpetrator aspects) focusing on meritocracy beliefs, emotional intelligence, and organizational culture. **Background.** Workplace bullying remains a major issue in nursing despite decades of research and policy-making. Therefore, comprehensively understanding the individual and institutional factors affecting workplace bullying from both the victim and perpetrator perspectives is crucial. **Methods.** In October 2022, 379 nurses working in South Korean tertiary hospitals were surveyed using a self-reported online questionnaire. Meritocracy beliefs, emotional intelligence, workplace bullying experiences, and nursing organizational culture were measured using the Meritocracy Belief Scale, Wong and Law Emotional Intelligence Scale, Negative Acts Questionnaire-Revised, and Positive Nursing Organizational Culture Measurement Tool, respectively. **Results.** Gamma regression analysis revealed that, for workplace bullying, the factors influencing the victim aspect were the experience of witnessing bullying in the workplace, organizational culture, and meritocracy beliefs. In contrast, the factors affecting the perpetrator aspect were emotional intelligence, meritocracy beliefs, and experience of bullying at work. **Conclusion.** Decreasing nurses' degree of meritocratic hubris in a positive organizational culture and increasing their emotional intelligence are necessary to prevent and intervene in workplace bullying. **Implications for Nursing Management.** Targeted approaches are needed to address and mitigate the detrimental effects of factors influencing workplace bullying. These approaches could include interventions that improve nurses' emotional intelligence, assess their level of meritocracy beliefs, and offer opportunities for self-reflection on meritocratic hubris. Such initiatives may be necessary to effectively tackle workplace bullying and promote a healthier nursing work environment.

1. Introduction

Workplace bullying has remained an ongoing problem in nursing for the last four decades and threatens to persist in the future [1, 2]. It results in negative consequences for individual nurses, patients, and organizations worldwide [1, 3]. The factors that cause workplace bullying are diverse, and to understand workplace bullying in the nursing profession, integrating both individual disposition and institutional factors is necessary [4]. According to a cross-cultural scoping review [5] and a systematic review [6], the factors influencing workplace bullying among nurses are divided into two levels, individual and institutional. For

individual-level antecedents of workplace bullying, demographics (gender, age, marital status, working experience, education level, etc.) and personality traits were reported. Institutional-level antecedents included work characteristics, such as work overload, staffing, working condition, leadership style, and organizational culture. These two types of factors are not mutually exclusive; thus, workplace bullying is often perceived as an outcome of interactions between these two factors [7]. In this study, as potential factors affecting workplace bullying, we focused on meritocracy and emotional intelligence at the individual level and organizational culture at the institutional level. Previous studies have mainly been limited to the victim aspects of workplace

bullying, largely ignoring perpetrator aspects [2]. In the few studies on perpetrator aspects, in line with the incivility spiral effect [8], it was only found that the more workplace bullying was experienced, the higher reciprocated perpetration [9]. In this regard, identifying factors associated with workplace bullying victim and perpetrator aspects and creating intervention plans for both aspects are necessary in nursing management [2, 10]. This study integrates discussions from the perspectives of both victims and perpetrators regarding workplace bullying among nurses.

Meritocracy is a concept proposed by Young [11], referring to a fair and equitable system of gaining resources, status, and rewards based on individuals' intelligence, abilities, achievements, and efforts. In the nursing context, it refers to the idea of promoting and advancing nurses based on their skills, knowledge, and contributions to the field [12]. Contemporary youth highly value processes linked to ability [13]. The combination of meritocracy and fairness is known as "meritocratic justice," which refers to the expectation of achieving fairness based on meritocracy [14]. The meritocratic justice is associated with the perception that acquiring resources and status based on ability or effort is justifiable [15]. Furthermore, meritocratic belief refers to a strong belief in the expectation of achieving fairness based on meritocracy. This belief can lead to a preference for intense competition and decreased sensitivity to inequality [15]. Consequently, meritocratic beliefs may cause nurses to attribute their success or desirable behavior to internal factors such as ability or effort, while blaming external factors such as luck or situational idiosyncrasies for their failures or undesirable behaviors. According to a longitudinal study [16], endorsing meritocratic beliefs during their youth has affected their own socioeconomic status across their life span. Such attributions can hinder mutual understanding and potentially contribute to workplace bullying among nurses. Moreover, meritocratic beliefs may lead to the exclusion or devaluation of individuals who do not fit traditional merit-based criteria [17]. This can be explored in the nursing context by examining how meritocratic ideals inadvertently perpetuate inequality or hinder diversity and inclusion in the profession. Based on these backgrounds, we hypothesized that stronger meritocracy belief can influence workplace bullying experiences from the perspectives of both victim and perpetrator (hypothesis 1).

Emotional intelligence encompasses the ability to monitor and comprehend one's own emotions, as well as those of others, and utilize this information to guide decision-making and actions [18]. In healthcare professions, high levels of emotional intelligence have positive effects on compassionate care and nursing performance [19, 20]. Extensive research has established a correlation between nurses' emotional intelligence and important aspects of their practice, including person-centered care [21], nursing productivity [22], and nursing care quality [23]. Additionally, emotional intelligence contributes positively to the performance of caring roles among nurses in multispecialty hospital settings [24]. Notably, emotional intelligence enables the effective management of both patients' needs and

demands within work relationships, leading to increased collaboration among nurses [18, 25]. Nurses with a low profile of emotional intelligence may become perpetrators of workplace bullying [10]. Nurses themselves acknowledge the importance of emotional intelligence as a quality that underpins their effectiveness as healthcare professionals and leaders, aids the understanding of others' needs and concerns, and facilitates individualized care [26]. Consequently, emotional intelligence can mitigate or prevent workplace bullying by promoting an understanding of one's own emotions, as well as the emotional dynamics among fellow nurses. We hypothesized that lower emotional intelligence significantly contributes to workplace bullying experiences from the perspectives of both victim and perpetrator (hypothesis 2).

Nursing organizational culture refers to the shared values, beliefs, and behaviors among nurses within an organization that are acquired by and transmitted to colleagues and significantly shape thoughts and actions [27, 28]. It has been identified as a crucial organizational factor that influences workplace bullying [29, 30]. Nurses who are bullied may passively accept or endure bullying because of the belief that reporting it will be ineffective, thereby highlighting the cyclical nature of bullying fostered by ingrained organizational cultures [31]. Different types of organizational cultures—such as those that are relationship-oriented, hierarchical-oriented, performance-oriented, and innovation-oriented—have significant effects on workplace bullying [29, 32, 33]. Positive organizational culture among tertiary hospital nurses was associated negatively with the workplace bullying victim aspect [10]. Thus, we hypothesized that a less positive organizational culture can influence workplace bullying experiences from both victim and perpetrator perspectives (hypothesis 3).

Addressing bullying is crucial given its prevalence and impact on unhealthy work environments [5]. In addition, with the increasing use of social media platforms and internal communication systems in hospitals, both face-to-face bullying and cyberbullying have become more prevalent [28]. According to a systematic review on interventions for nurses' workplace bullying [34], all the interventions enhancing communication skills, interpersonal relationships, assertiveness, trust, and empowerment were effective. These strategies enhancing self-reflection and empathy can be introduced to solve interpersonal conflicts and workplace bullying [34, 35], and are in line with developing effective interventions identifying meritocracy and emotional intelligence as factors affecting workplace bullying is crucial. Furthermore, the goal was to gain insights into the dynamics of workplace bullying in terms of victim and perpetrator aspects and contribute to the development of effective intervention strategies for creating healthier and more supportive nursing environments.

2. Materials and Methods

2.1. Study Design. A cross-sectional survey was conducted in accordance with the STROBE guidelines [35].

2.2. Participants and Data Collection. The inclusion criteria were as follows: (1) nurses working at tertiary hospitals in South Korea, (2) incumbent nurses providing direct and indirect care, and (3) nurses belonging to the nursing department. The exclusion criteria were as follows: (1) nurses working at secondary- or lower-level hospitals, and (2) newly graduated nurses in their probationary period (less than three months) considering that nurses are under special protection, supervision, and guidance of the nurse manager. Healthcare professionals in tertiary care settings are required to be highly specialized and experienced [36, 37]. They are exposed to risks of high levels of work stress and burnout [38] and are prone to experience workplace bullying. Considering known antecedents of workplace bullying among nurses [5], we have limited the institution level to tertiary hospitals. This study was conducted through an online survey using a link; there was no restriction on participants' geographical location (including all regions of South Korea).

To determine the required sample size for multiple regression analysis, the researchers utilized the software G*Power 3.1.9.2, with a significance level of 0.05, a power ($1-\beta$) of 0.80, 13 predictors, and an effect size (f^2) of 0.06 [10]. The calculated minimum sample size was 309. Considering a potential dropout rate of approximately 10% based on a previous online research study [39], the researchers posted an online survey link on the online community for nurses most frequently visited as an open call invitation. A warning was displayed to the participants not to respond more than once. Data collection occurred between October 27 and November 1, 2022, with a target of 345 participants. Although 440 responses were collected, the analysis included 379 participants after excluding 45 who were not workers at a tertiary hospital and 16 who were not belonging to the nursing department. All respondents received a coffee voucher after completing the online survey (worth \$5).

2.3. Ethical Considerations. After receiving approval from the institutional review board of the authors' university (approval number: blinded for review, granted on September 7, 2022), the study was conducted in accordance with the guidelines outlined in the Declaration of Helsinki. To ensure ethical considerations, the research participants were provided with a comprehensive explanation detailing the research purpose, methodology, assurance of anonymity, option to withdraw from participation at any point if desired, and commitment to destroy all related information upon completion of the study. Following the provision of this information and electronic informed consent, the participants completed a questionnaire as part of the research process.

2.4. Instruments. Data on participants' sociodemographic (sex, age, marital status, religion, education level, and subjective health status) and work-related characteristics (total working years, current working unit, position, workplace bullying prevention training, and experience of

workplace bullying) were obtained using a self-report questionnaire specifically developed for this study by the researchers. Validated instruments were used to assess meritocracy, emotional intelligence, organizational culture, and workplace bullying (victim and perpetrator aspects). Permission to use the Korean versions of these instruments was obtained from the original researchers and authors.

2.4.1. Meritocracy Belief. The Meritocracy Belief Scale [14] was used to measure belief in meritocratic justice. It consists of eight questions on a 6-point Likert-type scale (1 = not experienced at all and 6 = very strongly experienced), and the scores range from 8 to 48 points. In the original study, the tool's convergent, discriminant, and content validity were verified, and Cronbach's $\alpha=0.83$ [15]. In this study, Cronbach's $\alpha=0.79$.

2.4.2. Emotional Intelligence. Emotional intelligence was assessed using the Wong and Law Emotional Intelligence Scale, originally developed by Wong and Law [40] and adapted and validated in the Korean language by Jeong et al. [41]. This scale consists of 16 items in the following sub-domains: self-emotional appraisal, others' emotional appraisal, regulation of emotion, and use of emotion. Each item is rated on a 7-point Likert scale, and the total score ranges from 16 to 112 points, with higher scores indicating higher levels of emotional intelligence. The internal consistency reliability of the original scale was reported as Cronbach's $\alpha=0.76$ to 0.89 [40], whereas in the Korean version, Cronbach's $\alpha=0.88$ (0.80 to 0.89) [41]. In this study, Cronbach's $\alpha=0.90$ (0.80 to 0.88).

2.4.3. Organizational Culture. The Positive Nursing Organizational Culture Measurement Tool [42] was used to assess organizational culture. It comprises 26 items divided into the following subfactors: positive leadership of the nursing unit manager, pursuit of common values, formation of organizational relationships based on trust, and a fair management system. Each item is rated on a 5-point Likert scale ranging from 1 (not at all) to 5 (very much so). The total score ranges from 24 to 120 points, with higher scores indicating a stronger recognition of the positive aspects of the nursing organizational culture. The internal consistency reliability of the scale in the original study was Cronbach's $\alpha=0.95$ (0.83 to 0.95) [42]. In this study, Cronbach's $\alpha=0.96$.

2.4.4. Workplace Bullying Experiences. The Korean version [43] of The Negative Acts Questionnaire-Revised (NAQ-R) [44] was used to assess workplace bullying experiences from the victim's perspective. The NAQ-R defines victims of workplace bullying as those who experienced direct and indirect aspects of work-related bullying, person-related bullying, or physical intimidation [44]. The NAQ-R consists of 22 items (i.e., being humiliated or ridiculed in connection with your work and having allegations made against you) rated on a 5-point Likert scale. The total score ranges from 22 to 110 points, with higher scores indicating

more severe workplace bullying. The internal consistency reliability of the original scale was reported as Cronbach's $\alpha = 0.93$ [44], while in the Korean version, Cronbach's $\alpha = 0.93$ [43]. In this study, Cronbach's $\alpha = 0.96$.

The Negative Acts Questionnaire-Perpetrator (NAQ-R-P) [45; currently under publication] was used to measure workplace bullying experiences from the perpetrator's perspective. The items of the NAQ-R-P were constructed by modifying items from the NAQ-R [44] that focused on victim aspects, adjusting them to situations involving perpetrators. The NAQ-R-P consists of 22 items rated on a 5-point Likert scale, with a scoring range of 22–110; higher scores indicate more severe workplace bullying instigation [44]. This scale is unidimensional, and its validity has been verified [45]. The Tucker–Lewis Index = 0.86, Incremental Fit Index = 0.90, Comparative Fit Index = 0.88, Normal Fit Index = 0.85, and Content Validity Index for the universal scale is 0.83 [45]. In the original study, Cronbach's α for the NAQ-R-P was 0.97 [45]. In this study, Cronbach's α was 0.97.

2.5. Data Analysis. The data were analyzed using IBM SPSS for Windows (version 26.0; IBM Corp., Armonk, NY, USA). Repeat participation in the survey link was strictly limited, and there were no missing values, as all questions were answered. Descriptive statistics were used to analyze the participants' sociodemographic and work-related characteristics, meritocracy, emotional intelligence, organizational culture, and workplace bullying. The normality of the variables was evaluated using the Shapiro–Wilk test. The normality assumption was not satisfied. Mann–Whitney U and Kruskal–Wallis tests were used to examine differences in workplace bullying (victim and perpetrator aspects) based on participants' sociodemographic characteristics. Spearman's rank correlation coefficient was used to assess the association among the major variables. Gamma generalized linear regression analysis was performed to determine the effects of the major variables on workplace bullying experiences (victim and perpetrator aspects).

3. Results

3.1. Participants' Sociodemographic and Work-Related Characteristics. Table 1 presents the sociodemographic and work-related characteristics of the participants. The participants' median age was 30.00 years (interquartile range: 27.00~37.00, minimum: 22.00, maximum: 55.00), and the majority were women, accounting for 352 (92.9%) participants in the total sample. Among the participants, 231 (60.9%) were unmarried, and 222 (58.6%) were non-religious. Regarding education, 280 (73.9%) participants held a bachelor's degree. In terms of occupation, 307 (81.0%) participants were registered staff nurses. The majority of participants (202, 53.3%) were currently working in general wards. The median of clinical experience was 6.00 years (interquartile range: 3.00~11.00). Furthermore, 230 (60.7%) reported completing workplace bullying prevention training in the past year; 88 (23.2%) reported experiencing workplace

bullying in the past year; 25 (6.6%) reported being workplace bullying perpetrators; and 149 (39.3%) reported witnessing their colleagues being bullied.

3.2. Differences in Victim and Perpetrator Aspects of Workplace Bullying by Sociodemographic and Work-Related Characteristics. The results of the analysis of the differences in workplace bullying (victim and perpetrator aspects) based on sociodemographic and work-related characteristics are presented in Tables 2 and 3, respectively. Table 2 shows that workplace bullying (victim aspect) was significantly higher among participants who reported their subjective health status as "not healthy," those who had experienced workplace bullying in the past year, and those who had witnessed workplace bullying in the past year. Similarly, Table 3 illustrates that workplace bullying (perpetrator aspects) was significantly higher among those who reported their subjective health status as "not healthy," those who had been victims of workplace bullying in the past year, and those who had witnessed workplace bullying in the past year.

3.3. Correlation among the Major Variables. Workplace bullying experiences (victim aspect) were positively correlated with meritocracy beliefs ($\rho = 0.13$, $p = 0.010$) and negatively correlated with emotional intelligence ($\rho = -0.10$, $p = 0.046$) and organizational culture ($\rho = -0.30$, $p < 0.001$). Workplace bullying experiences (perpetrator aspect) were positively correlated with meritocracy beliefs ($\rho = 0.16$, $p = 0.002$) and negatively correlated with emotional intelligence ($\rho = -0.17$, $p < 0.001$) and organizational culture ($\rho = -0.19$, $p < 0.001$). A significant positive correlation was found between the victim and perpetrator aspects of workplace bullying experiences ($\rho = 0.50$, $p < 0.001$) (Table 4).

3.4. Factors Affecting Workplace Bullying Experiences (Victim and Perpetrator Aspects)

3.4.1. Victim Aspect of Workplace Bullying Experiences. The variables that were significant at $p < 0.05$ in the analysis of differences in workplace bullying (victim aspect) based on participants' characteristics, as well as the variables that were correlated with the victim aspect, were included in the Gamma generalized linear regression model. Factors influencing the victim aspect of workplace bullying were witnessing workplace bullying, meritocracy beliefs, and organizational culture (Table 5). From the perspective of victim, hypotheses 1 and 3 were supported; however, hypothesis 2 was not.

3.4.2. Perpetrator Aspect of Workplace Bullying Experiences. The variables that were significant at $p < 0.05$ in the analysis of differences in workplace bullying (perpetrator aspect) based on participants' characteristics, as well as the variables that were correlated with the perpetrator aspect, were included in the Gamma generalized linear regression model. Factors influencing the perpetrator aspect of workplace

bullying were workplace bullying experiences, meritocracy beliefs, and emotional intelligence (Table 6). From the perspective of perpetrator, hypotheses 1 and 2 were supported; however, hypothesis 3 was not.

4. Discussion

This study aimed to investigate the factors influencing workplace bullying experiences from both victims' and perpetrators' perspectives, focusing specifically on meritocracy beliefs, emotional intelligence, and organizational culture. There has been sustained interest in developing and implementing various intervention programs and solutions aimed at preventing workplace bullying, which persists as a significant issue within organizational culture [5, 32, 33]. Nevertheless, this study shows that efforts to eradicate workplace bullying have not bridged the gap in the perception of victims and perpetrators, indicating a significant lack of awareness among perpetrators. Moreover, as the number of witnesses to workplace bullying exceeds the number of victims, those who experience workplace bullying often perceive it as a by-product of organizational culture rather than fully recognizing the seriousness of the harm they have suffered [30, 31]. Previous research has highlighted the critical role of nursing organizational culture in influencing workplace bullying, emphasizing the necessity of implementing specific strategies and organizational-level interventions to avoid a hierarchy-oriented culture [27, 29–31]. These studies demonstrate that nurses who have

been victims of workplace bullying often find it challenging to actively address the issue, with such repetitions frequently stemming from and reinforcing the characteristics of the organizational culture [29, 30].

The findings of this study revealed that several factors influenced the victim aspect of workplace bullying. Specifically, the experience of witnessing workplace bullying, meritocracy beliefs, and organizational culture emerged as significant factors associated with the occurrence of workplace bullying as a victim. Establishing an organizational culture rather than focusing solely on individual abilities or differences is crucial. Organizational initiatives aimed at cultivating an optimal workplace environment for nurses hold significance in enhancing nursing organizational culture [28, 46]. To date, various programs have been implemented at both individual and organizational levels to reduce the incidence of workplace bullying. For individual strengthening, initiatives such as depression and stress management and psychiatric counseling have been explored. On the organizational level, efforts have included participation in conflict management training programs, policies to facilitate smooth communication, and the application of social media within the hospital environment [34, 47, 48]. Both approaches must be easily accessible to the target audience, and integrating these initiatives into the organizational culture remains a future challenge.

Younger generations place a high value on meritocracy, and their stronger meritocracy beliefs can lead to uncertain outcomes and contribute to workplace bullying toward

TABLE 4: Correlations among variables ($N = 379$).

	Career length	Meritocracy belief	Emotional intelligence	Organizational culture	Workplace bullying (victim)	Workplace bullying (perpetrator)

others [14, 15, 17]. Relying solely on quantitative evaluation without relational assessment can also contribute to workplace bullying [32]. Therefore, incorporating qualitative evaluations alongside quantitative measures is necessary for a comprehensive understanding of individuals. For this reason, peer evaluation systems have been established in hospitals to maintain an appropriate level of meritocracy [49]. In addition, it is essential to employ various strategies to promote teamwork, beginning with fostering a relationship-oriented nursing organizational culture that emphasizes mutual respect and prevents careless treatment among health professionals [17, 28, 47]. Understanding the occurrence of workplace bullying, especially among colleagues, is intricately linked to the complexities of human behavior, and employing a naturalistic approach to inquiry can provide deeper insights into this phenomenon [50]. Efforts should be made to promote the significance of processes and relationships alongside tangible outcomes through a horizontal organizational culture and transparent communication channels.

This study identified several factors that influence the perpetrator aspects of workplace bullying. These factors included experience of workplace bullying as a victim, meritocracy beliefs, and emotional intelligence. This study underscores the significance of implementing strategies aimed at enhancing emotional intelligence as essential measures to prevent and mitigate future workplace harassment. Lu and Shorey found that nurses were aware of the importance of emotional intelligence in clinical practice,

demonstrated a strong interest in improving their emotional intelligence skills, and recognized potential obstacles to the development of emotional intelligence [26]. Improving emotional intelligence not only enhances the value of patient-centered, personalized nursing care but also fosters stronger relationships among nurse colleagues. Emotional intelligence is acknowledged as a valuable asset enhancing performance and fostering effective group cohesion among nurses, serving as a universal buffer and coping strategy for work-related stress [51]. However, despite recognizing the potential for improvement through learning and training, there remains a scarcity of emotional intelligence promotion and intervention programs specifically tailored to healthcare professionals [52]. Hence, we recommend that more nursing leadership and intervention studies be conducted to ascertain the role of enhanced emotional intelligence among nurses. In particular, efforts to strengthen emotional intelligence include managers incorporating emotional intelligence competencies as a key criterion in the recruitment strategy for new nurses and university professors enhancing educational curricula to better develop these competencies [51, 52]. It is imperative for nurse managers to adeptly understand and harness emotional intelligence competencies.

Among the factors influencing workplace bullying by perpetrators, the concept of meritocracy warrants a balanced discussion due to its potential for both positive and negative effects. If achievements are the sole focus, the prevalence of meritocracy beliefs may lead to justifying both workplace

bullying victimization and perpetration [15]. Balancing meritocracy beliefs to account for both nurses' care outcomes and their impact on patients' quality of life is essential for fostering a healthy and supportive workplace environment. Additionally, based on the results of this study, which identified the experience as a victim of workplace bullying as an influencing factor for the perpetrator, it supports existing research findings that victims change into perpetrators over time [53, 54]. It is essential to make individual or organizational efforts to avoid becoming a victim of workplace bullying and establishing an organizational culture for this is important.

4.1. Limitations. In the current study, data were collected through an online survey as an open call invitation and institutions could not be determined; therefore, it may have led to self-selection bias and institutional effects cannot be identified. In addition, organizational factors such as nurse staffing or other work environments were not investigated. In future research, employing a random multistage sampling is recommended, and institutional characteristic effects should be assessed through multilevel analysis. To understand the situation of the nursing field, the status of meritocracy beliefs, emotional intelligence, organizational culture, and workplace bullying experiences among the various clinical settings should be compared. Additionally, the use of only self-reported measures suggests the need to include objective indicators, such as observations of workplace bullying behavior, for a more comprehensive analysis. Furthermore, to increase the explanatory power of the influencing factors of victims and perpetrators, we must pay attention to relationships through mixed studies. Future research should explore the relationship between emotional intelligence, meritocratic beliefs, and organizational culture. Despite these limitations, this study provides valuable insights into the factors influencing workplace bullying among clinical nurses by examining the perspectives of both victims and perpetrators.

5. Conclusions

In nursing management, customized approaches are crucial for addressing the factors contributing to workplace bullying and mitigating its negative consequences. The findings highlight the importance of targeted interventions, such as evaluating the impact of meritocracy beliefs, fostering self-reflection on potential meritocratic hubris, and enhancing nurses' emotional intelligence. Establishing an organizational culture that prioritizes relationships, trust, and open communication rather than solely emphasizing individual abilities or differences is paramount. To prevent workplace bullying among nurses, the implementation of protocols to prevent disruptive behaviors and foster teamwork is essential. These initiatives are critical in effectively combating workplace bullying and creating healthier and more supportive work environments for nurses.

Data Availability

The data used to support the findings of this study are available from the corresponding author upon request.

Conflicts of Interest

The authors declare that they have no conflicts of interest.

Authors' Contributions

All authors have made significant contributions to the work described, sufficient to warrant listing within the authorship list, and have been involved in the drafting and development of this final manuscript.

Acknowledgments

This work was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF), which was funded by the Ministry of Education (grant no. 2022R1F1A1063441). This study examined the current situation and relationship between missed nursing care (MNC) and job satisfaction among frontline nurses in a hospital dedicated to treating COVID-19 patients in China. Many dedicated hospitals were constructed or refurbished to centrally manage patients with COVID-19. Most nurses and doctors in these hospitals were redeployed from other departments or hospitals. This may have compromised nursing quality and job satisfaction. The omission of nursing care is a critical factor in assessing nursing quality; therefore, focusing on both MNC and job satisfaction is essential. This cross-sectional study used convenience and snowball sampling techniques to recruit frontline nurses working in a hospital for treating COVID-19 patients from November to December 2022. The questionnaires used in this study included sociodemographic information, job satisfaction, and the MISSCARE survey. Differences in job satisfaction and MISSCARE scores among participants' demographic deviations were explored using the Mann-Whitney Z test (two groups) and the Kruskal-Wallis H test (three or more groups). The correlation between participants' job satisfaction and missed nursing actions was analysed using Spearman's correlation analysis. The analysis included 306 frontline nurses. Frontline nurses' job satisfaction was high, and their MNC was low. The highest MNC was "offer rehabilitation care and guidance to patients in need every day." The most reported reasons for the MNC were "urgent patient situations." In addition, the job satisfaction scale, MNC scores, and reasons for MNC scores showed statistically significant differences among participants' demographic variables. Moreover, this study identified a negative correlation between frontline nurses' job satisfaction and MNC. Frontline nurses' job satisfaction was high, and their MNC was low. Frontline nurses' demographics were shown to affect their job satisfaction, MNC, and reported reasons. Furthermore, participants' job satisfaction can influence the MNC. Tailored interventions aimed at maintaining low levels of MNC should consider frontline nurses' demographic characteristics and job satisfaction.

1. Introduction

Missed nursing care (MNC) refers to any aspect of required care that is omitted, either in part or in whole, or delayed [1]. Evidence has shown that missed nursing activities can negatively affect patient safety, nursing care quality, and nurses' job satisfaction [2, 3]. Prior studies indicate that the COVID-19 pandemic has challenged nurses' working patterns because of the additional workload and psychological challenges [4, 5]. The challenges associated with COVID-19

in traditional working patterns reduce nurses' efficiency and well-being and threaten nursing quality, patients' safety, and nurses' job satisfaction [6, 7]. Thus, it is pivotal to consider the MNC and job satisfaction for frontline nurses caring for patients with COVID-19.

Several scholars have investigated this issue. A systematic review of five studies revealed higher MNC incidents among COVID-19 patients during the initial wave, which reduced in the second wave compared to incidents involving non-COVID-19 patients; these studies had contrasting findings,

with some supporting and others contrasting the findings related to COVID-19 patients [8]. Two studies conducted in Sweden [9, 10] found that most nurses perceived the pandemic as having had a significant impact on the critical care workforce but less influence on MNC. A survey conducted in the Philippines [11] reported similar results, with MNC occurring at low levels. In Iran [12], Hosseini et al. (2022) reported that supportive and necessary care, such as “emotional support to the patient and/or family” and “feeding the patient when the food is still warm,” were missed more than any other form of care during the pandemic.

As mentioned previously, missed nursing activities can influence nurses’ job satisfaction. Evidence suggests that the adequacy of personal protective equipment, nurse staffing levels, and patient safety culture can predict nurses’ satisfaction during COVID-19 [11, 13]. Lavoie-Tremblay et al. (2022) found that nurses caring for COVID-19 patients experienced high chronic fatigue, poor quality of care, lower work satisfaction, and a higher intention to leave their organisation [14]. By contrast, Giménez-Espert et al. (2020) found that frontline nurses’ satisfaction level was high [15].

These diverse results indicate that medical systems and policies vary among countries. For example, China suggested that COVID-19 patients should be collectively treated to contain the spread of the virus efficiently [16]. Consequently, many dedicated hospitals were promptly built or rebuilt [17]. As most dedicated hospitals did not have workers, healthcare workers from other hospitals or provinces were deployed [18]. To prevent these workers from becoming potential sources of infection, they were required to remain on-site until new workers arrived or until they completed their treatment duty [19]. Furthermore, they had to test negative for the disease at the end of the quarantine period before returning home. Unfamiliar work environments, dynamically changing personnel, exposure to the disease, a lack of experience in their new positions, and isolation from family members may have posed significant challenges to their work quality [11, 20]. Owing to these different national conditions, few studies have examined frontline nurses’ job satisfaction and MNC in hospitals dedicated to COVID-19 in China. Researchers have postulated that there may be differences between China and other countries.

This study aimed to analyse the status and relationship between job satisfaction and MNC among frontline nurses in a hospital dedicated to COVID-19 in China. The findings of this study provide valuable insights for nursing managers and policymakers in the future.

2. Materials and Methods

2.1. Study Design and Settings. This cross-sectional study was conducted anonymously in a hospital dedicated to COVID-19 patients in China from November to December 2022, using convenience and snowball sampling techniques. This study was approved by the institutional review board.

2.2. Participants. All nurses deployed to Jiangjunshan Hospital in Guizhou Province to care for COVID-19 patients were eligible for this anonymous cross-sectional study. The inclusion criteria were that the nurses should have worked in the hospital for at least one month, should have provided nursing care directly to COVID-19 patients, could read and fill out a questionnaire, and had volunteered to participate. The exclusion criteria included not completing the questionnaire on time or taking less than 180 seconds (a pilot test in which 30 participants completed the questionnaire showed that reading and completing the questionnaire carefully took a minimum of 180 seconds).

The sample size was calculated using a method introduced by Wang and Ji (2020) and MNC proportions during the COVID-19 pandemic by Falk et al. (2022) [9, 21], considering a 15% invalid questionnaire rate. Therefore, the final sample size was determined as 284.

2.3. Measures

2.3.1. Participants’ Demographic Profiles. The researchers created the demographic profiles questionnaire (including gender, age, educational background, marital status, number of children, family support, friends support, professional titles, original hospital level, original hospital type, working departments in their original hospital and the dedicated hospital, position in their hospital, serving years, working days in the dedicated hospital, working hours per shift and week in the dedicated hospital, and time spent working in the dedicated hospital).

2.3.2. Participants’ Job Satisfaction. Frontline nurses’ job satisfaction was measured using the Chinese version of the job satisfaction scale translated by Kachie Tetgoum (2021) [22] and developed by Paek et al. (2015) [23]. The scale comprised five items. Each item is answered on a 7-point Likert scale ranging from 1 (extremely dissatisfied) to 7 (extremely satisfied). To present the results better, the researchers divided the job satisfaction results into three levels: low (5–15), medium (16–25), and high (26–35), based on the total score of the questionnaire.

2.3.3. Participants’ MISSCARE Survey. The third section analysed the MNC and the reasons, using a Chinese version of the MISSCARE Survey from Si (2019) [24]; the original was created by Kalisch and Williams (2009) [1]. The survey had two parts: Part A (nursing care actions) included 24 items, and Part B (reasons for missed care) contained 19 items. The MNC items were answered on a 5-point Likert scale ranging from “always missed” to “never missed.” Another 19 items on the reasons for MNC were based on a 4-point Likert scale ranging from “significant reason” to “not a reason for MNC.”

To better present the results, the researchers divided the MNC results into three levels—low (24~56), medium (57~88), and high (89~120)—based on the total score in

section A. To treat all variables dichotomously, the researchers defined MNC in section A as reported “occasionally,” “frequently,” or “always,” similar to the MNC in the study by Falk et al. (2022) [9]. Furthermore, the researchers deemed the rate for each item of the MNC as high-incidence when its percentage was more significant than 50%, whereas those equal to or lower than 50% were low-incidence MNC.

The researchers also divided the reasons for the MNC survey into three levels—low (19~37), medium (38~57), and high (58~76)—based on the total score in section B. In addition, the researchers adopted the method used in Falk et al. [9] to regard “significant” and “moderate” reasons as considered reasons for MNC. Furthermore, this study also deemed each item’s occurrence rate as a high-incidence reason when its percentage was more significant than 50% and as a low-incidence reason when its ratio was equal to, or lower than, 50%.

2.3.4. Reliability and Validity. According to the study by Kachie Tetgoum (2021) [22], the reliability of the Chinese version’s Job satisfaction scale (Cronbach’s alpha, α) was 0.88, indicating that this scale is a reliable tool for assessing nurses’ job satisfaction.

Based on Si’s (2019) results [24], the Chinese version of MISSCARE Survey’s content validity index (CVI) for MNC and its reasons were 0.98 and 0.94, respectively, and their internal reliability (Cronbach’s alpha, α) were 0.93 and 0.92, respectively, indicating that it is a reliable tool for assessing MNC.

Owing to the different participants in this and other studies, a pilot survey with 30 participants was conducted to test the reliability of the scales in this study. The participants’ inclusion and exclusion criteria were the same as those of the survey participants mentioned above. The test results showed that the Job satisfaction scale’s reliability (Cronbach’s alpha, α) was 0.951 and the validity (Kaiser–Meyer–Olkin, KMO index) was 0.83. For the MNC questionnaire, the reliability (Cronbach’s alpha, α) was 0.998 and its validity (KMO) was 0.835. Regarding the reasons for MNC questionnaire, the reliability and validity were 0.987 and 0.774, respectively, indicating that the questionnaires used in this study were reliable tools for this study.

2.3.5. Data Collection. The data were collected between November and December 2022. The nursing staff in the research location was in workgroups on social media (WeChat) when they were deployed to the dedicated hospital. These workgroups have not yet been dissolved. First, the researchers posted a letter to the workgroups introducing the survey’s aim, content, and instructions. Furthermore, the researchers emphasised that each nurse would participate in the study voluntarily and anonymously. Second, the final questionnaires were imported into a survey website (<https://www.wjx.cn/>), and the questionnaire link was shared with frontline nurses in the workgroups. Third, when respondents clicked on the link, they could see two options: “willing to participate” and “unwilling to participate.” Only participants who selected “willing to participate” could open the complete

questionnaire. Thereafter, they could see an opening to the questionnaire introducing the aim, content, and instructions, and they participated in the survey through their accounts. In addition to frontline nurses who had left the workgroup, researchers contacted familiar frontline nurses who have worked at Jiangjunshan Hospital to recruit more nurses using a snowball sampling technique.

2.3.6. Data Analysis. Software SPSS v22.0 (IBM Inc., Armonk, NY, USA) was used to analyse the data. Data were presented as frequencies, percentages, means (standard deviation, SD), and medians (IQRs). Skewness, kurtosis, and Q-Q plots were used to test data distribution. Considering the abnormal distribution of data in this study, differences in job satisfaction and MISSCARE scores among participants’ demographic deviations were explored using the Mann–Whitney Z test (two groups) and Kruskal–Wallis H test (three or more groups). The correlation between participants’ job satisfaction and missed nursing actions was analysed using Spearman’s correlation analysis. For all analyses, $p < 0.05$ were considered statistically significant.

3. Results

3.1. Participants’ Demographic Profiles. In total, 310 frontline nurses responded to the survey; however, six nurses took a short time to complete the questionnaire (less than 180 s). Therefore, 304 nurses were included in the statistical analysis. The results showed that 77.63% (236/304) of the participants were female. Nurses aged 31–40 years accounted for 56.58% (172/304), 90.13% (274/304) had a bachelor’s degree, 79.93% (243/304) were married, and 44.08% (134/304) had only one child. The detailed demographic information is presented in Table 1.

3.2. Participants’ Job Satisfaction. The results showed that most participants choose “often” or “always” as their answer for each item, and each item’s median (IQR) score was from 6 (1) to 7 (1). Participants’ total median (IQR) score of their job satisfaction in the dedicated hospital was 32 (5.75), a high-level score (i.e., 26~35), indicating that the participants’ satisfaction with each item was high. The details are listed in Table 2.

3.3. Participants’ Missed Nursing Action. The results from this study demonstrated that the percentage of MNC items varied from 17.43% (53/304) to 27.96% (85/304), indicating that each MNC provided low-incidence care (i.e., lower than 50%). In addition, item 1 had the highest score, and its median (IQR) was 2 (2); other items scored a median (IQR) of 1 (1); and the total median (IQR) score of the questionnaire was 32 (22), a low-level score (i.e., 24–56). The three significant missed nursing activities in this study were “offer rehabilitation care and guidance to patients in need every day,” “emotional support for patient and/or family,” and “patient teaching about illness, tests, and diagnostic studies.” Additional information is presented in Table 3.

TABLE 1: Participants' demographic characteristics.

Variables (N = 304)	Categories	Frequency	Percentage

Working hours per week in the dedicated hospital (hours)	21~30	123	40.46
	31~40	78	25.66
	41 or above	103	33.88

3.4. Participants' Reasons for Missed Nursing Care. This study found that the rate of each reason for missed care ranged from 18.09% (55/304) to 55.26% (168/304) and the median (IQR) for each item ranged from 1 (1) to 3 (2), with a total median (IQR) score of 37 (19), indicating that these were low-level reasons. However, the percentages of "urgent patient situations," "unexpected rise in patient volume and/or acuity on the unit," and "the nurse did no nursing work" items were greater than 50%, indicating that these three were high-incidence reasons for the MNC in this study. Other details are listed in Table 4.

3.5. Comparison between Job Satisfaction and the MISSCARE Scores among Participants' Demographic Characteristics. There were significant differences in frontline nurses' total job satisfaction scores by age ($p = 0.001$), marital status ($p = 0.022$), number of children ($p = 0.006$), professional title ($p = 0.021$), and original department ($p = 0.002$). Higher job satisfaction was identified among frontline nurses who were older, married, had children, and higher professional titles, and were not originally from the ICU or emergency departments.

Regarding the MNC scores, significant statistical differences ($p < 0.05$) were observed among participants of different ages, family support, friend support, hospital types, and original department. Nurses with sufficient social support and older nurses reported fewer MNC. Nurses from the emergency department scored higher MNC points than those from other departments.

In addition, the study found significant differences ($p < 0.05$) in the reported reasons scores among frontline nurses based on various demographic and work-related factors. These factors include gender, age, family support, friend support, original hospital type, original department, time spent working in the dedicated hospital, working department in the dedicated hospital, and working hours per shift in the dedicated hospital. Frontline nurses who were male, younger, lacked support from family and friends, worked in comprehensive hospitals, originally worked in the ICU and emergency departments, worked in the dedicated hospital's ICU, and worked four to six hours per shift reported higher reasons scores. Detailed information is provided in Table 5.

3.6. The Correlations (Spearman) between the Respondents' Job Satisfaction and Their Missed Nursing Care Scores. The researchers used the total score of the MISSCARE A questionnaire as the dependent variable and the total score of the job satisfaction questionnaire, as well as each item's score of the job satisfaction questionnaire, as independent variables. Spearman's test was used to analyse the correlation

because the data had an abnormal distribution. The results revealed a negative correlation between participants' job satisfaction and missed care action scores. In addition, each item in the job satisfaction questionnaire was negatively correlated with missed nursing actions (Table 6). These findings suggest that frontline nurses with higher job satisfaction tend to miss fewer nursing care actions.

4. Discussion

Both the quality of nursing care and nurses' job satisfaction has been crucial issues in healthcare systems. MNC is an essential quality indicator in clinical practice that can influence nurses' job satisfaction. Therefore, this study analysed the current situation of MNC and job satisfaction among frontline nurses in a dedicated hospital in China. Based on the results, frontline nurses' job satisfaction was high while their MNC was low. Job satisfaction among participants can still influence MNC, ultimately affecting the quality of nursing care provided.

4.1. Frontline Nurses' Job Satisfaction. This study's results showed that frontline nurses in the dedicated hospital had high job satisfaction levels. These findings suggest that frontline nurses were satisfied with their work environment in the dedicated hospital. However, these results differ from those of other studies exploring frontline nurses' job satisfaction during the COVID-19 crisis. Wang et al. (2022) reported that frontline nurses in Wuhan experienced moderate levels of compassion satisfaction during the first wave of the pandemic in Wuhan [25]. By contrast, our study was conducted at the end of 2022, the third year of the pandemic, when healthcare workers had gained more experience and skills and could adequately prepare for and cope with the pandemic. Giménez-Espert et al. (2020) found that frontline nurses' satisfaction was high [15], whereas Falk et al. (2022) reported that nurses' job satisfaction improved as the pandemic progressed [9]. Frontline nurses' job satisfaction was higher in the second wave than in the first. This study confirms the reasons for the differences between the two studies.

4.2. Frontline Nurses' Missed Nursing Care. This study's results demonstrate that the frontline nurses' MNC was low. Von Vogelsang et al. (2021) reported the presence of MNC during the COVID-19 pandemic [10]. However, their results showed a higher percentage of MNC compared to that shown in this study, such as the two items' occurrence percentages being more significant than 50% in their research. By contrast, the highest incidence rate in this study was only 27.96%. A study in Iran by Hosseini et al. (2022)

(5) I am satisfied with the support provided by this hospital	-0.298	<0.001**

Note.* $p < 0.05$ ** $p < 0.01$.

[12] reported that “emotional support for patient and/or family,” “feeding patient when the food is still warm,” and “patient teaching about illness, tests, and diagnostic studies” were frequently missed items during the pandemic. Falk et al. (2022) also examined missed nursing during the first (November 2020) and second waves (May 2021) [9], finding that some items occurred more, while others occurred less, than did those in this study. In their research, the occurrence of “feeding patient when the food is still warm” and “setting up meals for the patient who feeds themselves” was 71.4% in the first wave and 79.4% in the second wave, respectively. The inconsistent results among these studies may be attributed to different survey times, places, and participants. A systematic review revealed a heightened incidence of MNC among COVID-19 patients during the initial wave and a diminished occurrence in comparison with non-COVID-19 patients in the second wave [8], which conformed to our postulation.

4.3. Frontline Nurses' Reported Reasons for Missed Nursing Care. Results from this study indicate that most reasons were low-incidence reasons, except for the “urgent patient situations” and “unexpected rise in patient volume and/or acuity on the unit” items. VonVogelsang et al. (2021) reported that the highest reasons for MNC were “unexpected rise in patient volume and/or acuity on the unit,” “urgent patient situations,” and “inadequate number of staff,” and their rates were from 32.4% to 79.8% in the first pandemic wave (May- June 2020) [10]. Falk et al. (2022) concluded that the most reported reasons for MNC in all samples were “inadequate staffing,” “urgent situations,” and “a rise in patient volume,” with rates ranging from 5.3% to 97.4% in the first wave and from 2.9% to 93.2% in the second wave [9]. Hosseini et al. (2022) reported that the significant reasons were “inadequate staff,” “urgent patient situations” (e.g., worsening of a patient's condition), and “unbalanced patient assignments.” Perhaps the different survey times, research locations, and participants could explain the inconsistent results among the three studies. For example, this survey was conducted from November to December 2022. Managers and administrators had prepared more adequately for the pandemic, and the supporting strategies and available supplies had improved. Labrague et al. (2022) found that nurse staffing levels and patient safety culture could predict MNC, confirming this study's findings [11]. In addition, the high-incidence reasons indicate that when staffing and

scheduling frontline nurses, nursing managers should adopt a flexible schedule to meet urgent clinical demands and determine frontline nurses' working scope to avoid nurses doing no nursing work.

4.4. Comparison between Job Satisfaction and MISSCARE Scores among Participants' Demographic Characteristics. First, this study's results indicated that frontline nurses who were older, married, had children, held higher professional titles, and were not originally from the ICU or emergency department showed higher job satisfaction. Generally, nurses with these characteristics receive more support from their families and original hospitals. Zhang et al. (2020) found that older healthcare workers enjoyed better mental health during the COVID-19 pandemic [26], which corroborates the findings of this study. Nurses who originally worked in the ICU or emergency department showed lower job satisfaction, possibly because of their newly allocated units and high job requirements. When staffing and scheduling nurses, nursing managers tended to allocate nurses with experience in the ICU and emergency department to the ICU, where they faced critically ill patients. González-Gil et al. (2021) suggested that critical care and emergency nurses could be categorised as vulnerable populations owing to high workloads, high patient-nurse ratios, shift work, and deficiencies in communication [27]. These reasons may explain the present study's results. Therefore, nursing managers should focus on the needs and conditions of frontline nurses and offer targeted support and assistance.

Second, this study demonstrated that older participants who lacked adequate social support scored higher on the overall missed nursing action questionnaire. One potential reason for this could be that, as nurses' age grow, their experiences and knowledge increase, which could help them deal with job demands. As mentioned previously, older healthcare workers enjoy better mental health [26]. In addition, nurses with sufficient family and friend support had lower MNC scores, which may contribute to better social support. Nurses with such backing may also be more engaged in their work, resulting in less missed care. Thus, nursing managers should consider frontline nurses' age, family and social support, and their original departments to reduce MNC.

Third, this study found that nurses from comprehensive hospitals who were originally from the emergency department and intensive care unit had higher MNC scores.

Nurses in specialised hospitals tend to have more experience in specific specialties, and when they move to a dedicated hospital, they can provide better care to patients in that area. However, nurses from comprehensive hospitals may face more choices surpassing their skill set, leading to a higher occurrence of MNC. Labrague et al. (2022) reported that hospital facility size could affect MNC [11], which is consistent with the findings of this study. Moreover, frontline nurses who worked in emergency departments and intensive care units were originally prone to being assigned to intensive care units in dedicated hospitals. Lobo et al. (2022) found that critical care nurses were disproportionately affected by the COVID-19 pandemic [28], and González-Gil et al. (2021) emphasised that critical care and emergency nurses can be categorised as vulnerable populations [27]. Thus, nursing managers should consider frontline nurses' original departments and hospital types to allocate nurses reasonably and thus maintain a low-level MNC.

Regarding the participants' serving years and gender, the results of Hosseini et al. (2022) showed that nurses with more than 10 years of work experience performed better than did those with less than 10 years of experience [12], which is consistent with the findings of this study. However, this study showed no statistically significant difference in MNC based on years of service. In addition, Hosseini et al. (2022) reported that the gender of nurses was significantly related to MNC ($p = 0.002$), with MNC being significantly lower among male nurses than among female nurses. However, this relationship was not observed in the present study.

Furthermore, Hosseini et al.'s (2022) study found that 8-hour and 12-hour rotation shifts had the highest rate of missed necessary care, whereas 7-hour shifts had the lowest rate of MNC [12]. These results are inconsistent with this study's findings, probably due to the shorter shift duration in this study, whereby most frontline nurses (86.18%) reported working for 4–6 hours per shift. In summary, nursing managers should consider frontline nurses' age, family and friend support, hospital type, and original department to reduce MNC.

Finally, the survey results indicated higher scores for male and younger frontline nurses, those with inadequate support from family and friends, those working in comprehensive hospitals or the dedicated hospitals' ICU, and those who originally worked in the ICU and emergency department and had a 4–6 hours working shift. Zhang et al. (2020) highlighted the varying levels of distress and depression experienced by the different genders [26]. In addition, a lack of social support can negatively affect nurses' emotional states, particularly those working in comprehensive hospitals, ICU, and emergency departments. Furthermore, Liu et al. (2022) found that frontline nurses in severe isolation wards worked shorter shifts of four hours compared to those in fever clinics and observation wards, who worked for 6–8 hours [29]. However, nurses who worked in 2021 and 2022 may have reported higher scores than those who worked in 2020 because of memory deviation over time. Therefore, nursing managers should prioritise frontline nurses' work conditions to enhance nursing quality.

4.5. The Correlations between the Frontline Nurses' Job Satisfaction and Their MNC. This study found a negative correlation between job satisfaction and missed care. In addition, this study also indicated that nurses miss less nursing care when they are more satisfied with their jobs, fellow workers, supervisors, hospital policy, and hospital support. A study by Gurková et al. (2022) in Czech acute care hospitals during the COVID-19 pandemic identified that overtime work, nurses' perception of the "Nursing foundations for the quality of care," and their satisfaction with their current position could predict the incidence of missed care [30]. Falk et al. (2022) determined that MNC could influence both patient outcomes and nurses' work environments [9], and that bedside nurses should develop quality indicators in critical care to address the reasons for MNC. In addition, Gurková et al. (2022) indicated that monitoring the conditions and aspects of the nurse work environment in hospitals and continuously considering nurses' concerns about the work environment on an ongoing basis are essential strategies for nurse supervision and for policymakers [30]. Labrague and de Los Santos (2021) pointed out that decreased job satisfaction could increase the fear of COVID-19 and chronic fatigue, and that resilience could reduce the effects of pandemic fatigue on clinical nurses' mental health, sleep quality, and job contentment [7]. This study confirmed the findings of the present study and indicated that hospital managers could improve nurses' job satisfaction by improving their nursing quality through their jobs, fellow workers, supervisors, hospital policies, and hospital support.

4.6. Limitations and Recommendation. The limitations of this study are as follows. First, as this study was conducted using a questionnaire survey, self-report bias is an evident limitation. Second, this study only included frontline nurses in one dedicated hospital, which may limit its generalizability to other locations. Finally, this study was conducted at the end of 2022, and frontline nurses who worked at dedicated hospitals in 2020 and 2021 may have experienced memory deviations over time. Thus, multicentre, large-sample, and more objective assessment studies are required.

Frontline nurses are an essential group that determines service quality during the response to crises relevant to emerging infectious diseases. Nursing managers should pay attention to the nurses' needs and provide tailored support and assistance based on age, gender, marital status, social support, and working environment. In addition, the results indicated that hospital managers could improve nurses' job satisfaction by improving their nursing quality through their jobs, fellow workers, supervisors, hospital policies, and hospital support.

5. Conclusion

Frontline nurses' demographics can affect their job satisfaction, MNC, and reported reasons. As the pandemic progressed, frontline nurses reported improvements in job satisfaction and a reduction in the number of MNCs. However, it should be noted that job satisfaction among participants could still influence MNC, ultimately affecting the quality of nursing care provided.

6. Implications for Nursing Management

The COVID-19 pandemic is highly contagious and poses challenges to nurses' work efficiency and emotional health. To reduce the occurrence of MNC and enhance nursing quality, hospital administrators and nursing managers should focus on improving nurses' job satisfaction by improving their work environments, supporting their relationships with colleagues and supervisors, implementing effective hospital policies, and providing adequate hospital support. Policy-makers and nursing managers should thoroughly assess the factors influencing MNC, such as nurses' characteristics. To some extent, it is possible to maintain a low level of MNC under similar conditions in the future once policymakers and nursing managers use this information to make reasonable and feasible decisions or policies.

Data Availability

The data that support the findings of this study are available from the corresponding authors and the first author upon reasonable request.

Ethical Approval

This study was approved by the Ethics Committee of the Affiliated Hospital of Zunyi Medical University (KLL-2020-283, approval date: 30 December 2020) and the Ethics Review Board of Philippine Women's University (ERB2022_0092, approval date: 17 November 2022) based on the principles of the Declaration of Helsinki. All eligible frontline nurses were informed of the study and its ethical principles (e.g., voluntary participation, withdrawal, anonymity, and confidentiality). All data were saved in password-protected computers, and nobody, except the research team, had access to the data.

Conflicts of Interest

The authors declare that they have no conflicts of interest.

Authors' Contributions

Xia Zhang and David contributed to the study conception and design. Jing Zhou, Fang Chen, and Zhixia Jiang contributed to data acquisition. Xia Zhang and Jing Yang analysed and interpreted the data. Xia Zhang, Jing Zhou, and David drafted and refined the manuscript. All the authors critically revised the manuscript for important intellectual content. All authors agree to be accountable for all aspects of the work and have approved the final version for publication.

Acknowledgments

The researchers appreciate all frontline nurses who responded to the survey and the support of the Guizhou Science and Technology Development Fund (Qiankehe supporting [2020]4Y174). The researchers would also like to express their gratitude to those who offered help in conducting and refining this research.

Background. Nurses represent the largest occupational group within the health care system, comprising half of the global health workforce. Health care settings are facing severe shortages in countries worldwide, with nurse turnover being identified as the primary reason for this shortage. However, estimates of nurse turnover rates vary widely in the relevant literature. **Objective.** This meta-analysis aimed to investigate the global nurse turnover rate since 2000 and provide evidence-based assistance to health policy makers and hospital managers. **Methods.** A systematic search of the PubMed, Web of Science, Embase, CINAHL, and Cochrane Library databases was conducted for relevant articles from January 1, 2000, to February 1, 2023. This study included cross-sectional, cohort, and longitudinal studies. In the meta-analysis, further risk of bias, heterogeneity, and subgroup analyses were conducted. Stata 17.0 was used for all of the statistical analyses. **Results.** In total, 48,157 records were scrutinized in this study, and 21 investigations encompassing 213,314 nurses across 14 countries were eventually included. The global nurse turnover rate ranged between 8% and 36.6%, and the combined nurse turnover rate was 16% (95% confidence interval: 14%–17%). Subgroup analysis demonstrated that the turnover rate was 19% (95% CI: 14%–23%) in Asia and 15% (95% CI: 13%–17%) in North America. **Conclusions.** This meta-analysis analysed the literature published from January 2020 to February 2023 and demonstrated that the global nurse turnover rate was 16%. It is suggested that all medical and health institutions actively adopt relevant systems that can reduce the turnover of nurses and promote a more harmonious, healthy, and safe occupational environment for nurses to strengthen the sustainable development capacity of the nurse workforce.

1. Introduction

Currently, the global ageing population and the increasing burden of chronic diseases (2020) are putting considerable pressure on the health care system [1]. As the largest occupational group in the health care system, nurses play a key role in the provision of health services [2]. Currently, there are an estimated 200,000 nurses and 20,000 midwives worldwide, thus representing approximately half of the global human resources in the health sector [3]. Nurses account for more than half of Chinese health professionals. They are a major force in enhancing medical reform and improving services to benefit people. With the increasing demand for medical and health services, the global demand for nurses is also increasing rapidly (2022) [4]. Several studies have shown that the world is facing a severe shortage of nurses [4, 5]. From a concerning aspect, WHO has

estimated that the global number of nurses will decrease by approximately 7.6 million by 2030 [6]. Some studies have shown that the high turnover rate of nurses is one of the main factors leading to the global shortage of nurses [7, 8].

An increase in nurse turnover will have numerous adverse effects on the health care system. For example, a reduction in the number of experienced professional nurses will increase the lack of human resources and the workload of in-service nurses, thus affecting not only the construction and development of hospital nursing talent teams but also the quality of nursing services and medical safety [9, 10]. In addition, Warshawsky et al. reported that increased nurse turnover leads to an increase in the incidence of falls and stress injuries [11], and increased nurse turnover may even increase the occurrence of adverse outcomes such as patient death [12]. Moreover, the shortage of human resources and the increased turnover of nurses are closely related to the

high costs of recruiting and training new nurses [13]. As a result, nurse turnover is being closely evaluated by health policy makers, hospital managers, and health care institutions worldwide [14, 15]. Studies indicate that the consistent and accurate measurement of turnover is a crucial step in solving the problems of the organizational work environment and the management of nursing staff [16]. Therefore, it is imperative to gain a comprehensive understanding of the current state and variations in nurse turnover rates, which would be beneficial in implementing more effective strategies to reduce workforce attrition.

At present, many published cross-sectional studies have mostly included nurse turnover tendency as being the main outcome variable and explored the relationship between one or more groups of factors and nurse turnover tendency [17–20]. However, a greater turnover tendency may not lead to actual turnover, and an exploration of the situations or factors influencing nurses who have actually left their positions may be of more practical value and guiding significance. To the best of our knowledge, there are few internationally published articles on nurse turnover rates. Some recent studies have measured the turnover rate of nurses in emergency departments, ICUs, and obstetrics and gynecology departments. Several studies have also examined the turnover of nurses in specific countries or regions (such as the USA and South Korea). A comparative review of nurse turnover costs reported nurse turnover rates of 44.3%, 26.8%, 19.9%, and 15.1% in four countries, including New Zealand, the USA, Canada, and Australia, respectively [21]. Chen et al. reported that the turnover rate of nurses in Taiwan was 8.9%, which is low [22].

In conclusion, given that the turnover rate varies greatly among countries, it is necessary to assess the global combined nurse turnover rate with scientific methods and comprehensive retrieval strategies. The purpose of this study was to provide relevant information and evidence for health policy makers and hospital managers by conducting a comprehensive search and scientific analysis of the current literature.

2. Materials and Methods

This study was completed according to the Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) statement. The protocol was registered on PROSPERO (registration number: CRD42023389556).

2.1. Search Strategy. The PubMed, Web of Science, Embase, CINAHL, and Cochrane Library databases were searched for related articles from January 1, 2000, to February 1, 2023. To ensure that the relevant literature was collected as comprehensively as possible, a large set of search terms was used. These search terms were developed by using free terms and subject terms and combined with the Boolean operator OR/AND. The search terms included nurse*, attrition, leave*, turnover, and quit. The utilized search strategy for each database is provided in Appendix A. The exact combination of search terms was (attrition OR leave* OR turnover OR

quit) AND (nurse*). Furthermore, studies were selected by manually searching the references to determine the comprehensiveness of the search.

2.2. Inclusion and Exclusion Criteria. According to the PRISMA statement, the following inclusion criteria, which are shown by using the PICOS framework, were used: participants (P), clinical nurses working in the hospital (nurse practitioners (LPNs)); intervention (I), not applicable; comparison (C), not applicable; outcomes (O), overall turnover rates, or sufficient raw data for calculation; and study design (S), cross-sectional studies, cohort studies, and population-based longitudinal studies.

The exclusion criteria were as follows: (1) meeting, reviews, case reports, letters, or editorials; (2) studies for which the full text was not available; (3) studies with incomplete data; (4) articles published in languages other than English; and (5) studies with a sample size less than 100.

2.3. Data Extraction. The study selection process was performed by two investigators (LP and YC). After removing duplicate studies, the titles, abstracts, and full texts of the studies were independently screened by using the inclusion and exclusion criteria. Any disagreement between the two assessors was resolved by discussion with a third evaluator (RH).

The two evaluators independently extracted the following data by using standardized data sheets: author, year of publication, study time, country/region, study type, sampling method, survey method, sample size, turnover rate, data source, and participant characteristics (such as mean age and female ratio). A third evaluator (RH) verified the extracted data.

2.4. Risk of Bias Assessment. Two researchers used the bias risk assessment tool that was developed and designed by Hoy and colleagues to determine the internal and external validity of prevalence studies [23], aiming to evaluate the quality of the included studies. This evaluation tool contains two-item subscales (external validity and internal validity), totalling 10 items. Each item is scored as 1 (“yes,” “high quality”) or 0 (“no,” “low quality”). The total score for a study is pooled from all of the item scores. The total possible scores are 9, 6–8, and 0–5, thus representing high, medium, and low quality, respectively. Low-quality studies had a high risk of bias; therefore, they were excluded from this study. The risk of bias assessment was conducted by LP and counterchecked by YC, with discrepancies resolved by RH.

2.5. Data Synthesis. The turnover rate (p) was calculated via the following equation:

$$\text{Turnover rate } (p) = \frac{\text{nurse turnover (number of nurses)}}{\text{total number of nurses sampled } (N)} \quad (1)$$

The standard error (SE) of the nurse turnover rate [24] was computed by using the following formula:

$$SE = \sqrt{\frac{p(1-p)}{n}} \quad (2)$$

2.6. Data Analysis. Due to the heterogeneity between the studies, a random effect model with a confidence interval (CI) of 95% was used [25]. All of the statistical analyses were performed by using STATA 17.

Statistical heterogeneity was assessed by using the I^2 statistic, with I^2 values of 25%, 50%, and 75% indicating mild, moderate, and high heterogeneity, respectively. An I^2 value lower than 50% was considered to be acceptable [26]. Subgroup analyses were conducted for region, sample size (<1,653 and \geq 1,654 participants), time of survey initiation (2000–2008 and 2009–2019), year of publication (2003–2014 and 2015–2023), data sources, and departments. Moreover, to determine the factors associated with the nurse turnover rate, the hazard ratios (HRs) and 95% confidence intervals (CIs) of the influencing factors were combined and examined in a random effects model. Group analysis by sex, labour union, hospital size, work environment satisfaction, and job content satisfaction was performed to test the influence of relevant factors. Publication bias was assessed by using funnel plots and Begg's test [27], and the robustness of the findings was determined via sensitivity analysis. A $P < 0.05$ (two-sided test) was considered to indicate statistical significance.

3. Results

3.1. Summary of the Search Results. Twenty-one studies were ultimately included in this meta-analysis. Initially, 48,157 records were retrieved from 5 databases, of which 21,938 duplicates were removed, thus resulting in 26,219 studies. After screening the titles and/or abstracts, 193 studies were included in the full-text evaluation. According to the exclusion criteria, 69 studies were excluded due to inconsistent study type, 25 studies were excluded for being published in languages other than English, 30 studies were excluded for having incomplete relevant data, 5 studies were excluded for having a sample size <100, and 9 studies were excluded for being low-quality studies. Ultimately, the meta-analysis included 21 studies [16, 22, 28–46]. The details of the screening process are shown in Figure 1.

3.2. Description of the Included Studies. The characteristics of the 21 studies that were included in this meta-analysis are presented in Table 1. The studies were published between 2003 and 2023. These studies included 213,314 nurses from 14 countries with sample sizes ranging from 226 to 96,158. The age of the study participants ranged from 23 years to 46.9 years. Regarding the geographical regions, the number of studies conducted in Asia (8) and North America (7) was close. Conversely, Oceania, Europe, and Africa are represented equally, each contributing two studies to the analysis.

3.3. Methodological Quality. In this study, a methodological quality assessment of 21 studies was conducted by using the risk of bias assessment tool developed by Hoy and

colleagues, and details of the assessment process are provided in Table 2. Five studies exhibited high quality, achieving scores ranging from 9 to 10. Sixteen studies were of moderate quality, with scores between 6 and 8 points. The average quality score of the 21 studies was 7.

3.4. Pooled Prevalence of Nurses' Turnover. The distribution of turnover rates across the studies ranged from 8% to 36.6%. A study conducted in Jordan had the highest turnover rate, and a study conducted in the United States had the lowest turnover rate. Random effects models were used due to the significant degree of heterogeneity ($I^2 = 98.61\%$, $P < 0.01$).

The meta-analysis demonstrated a global nurse turnover rate of 16% (95% CI: 0.14, 0.17). Figure 2 shows the forest plots obtained from the meta-analysis. The funnel plot showed asymmetry (Figure 3), and Begg's test showed that there was no significant publication bias ($P = 0.695$).

3.5. Sensitivity Analyses. A sensitivity analysis was conducted on the 21 articles included (Figure 4) using Stata 17 to assess the robustness of the meta-analysis results. After eliminating each single study, there was no significant difference between the combined effect value and the total combined value, thus indicating that the results of this study had good stability.

3.6. Subgroup Analyses. To explore the sources of heterogeneity, we performed subgroup analyses based on region, sample size, study start time, publication year, data sources, and departments (Table 3). The study demonstrated that the turnover rate of nurses in Asia (19%; 95% CI: 0.14, 0.23) was greater than that in North America (15%; 95% CI: 0.13, 0.17), but there was no significant difference between the subgroups. Similarly, no significant differences were found across varying sample sizes (Figure 5).

According to a subgroup analysis by year of publication, the global nurse turnover rate was higher from 2003 to 2014 at 17% (95% CI: 0.14, 0.21) compared to 14% from 2015 to 2023 (95% CI: 0.12, 0.16). Analysis by study start time showed turnover rates of 18% (95% CI: 0.14, 0.21) from 2000 to 2008 and 13% (95% CI: 0.12, 0.16) from 2009 to 2019, with this difference being statistically significant ($P = 0.025$) (Figure 6).

Subgroup analysis by the data source revealed that global nurse turnover rates were higher in studies using databases at 18% (95% CI: 0.16, 0.20) compared to those using hospital data at 12% (95% CI: 0.10, 0.15), a statistically significant difference ($P < 0.001$) (Figure 7).

Five articles reported on the turnover rate of department nurses [22, 38, 41, 44, 45]. According to the subgroup analysis by department, the turnover rate of ICU nurses was 23% (95% CI: 12%–34%) and the turnover rate of obstetrics and gynecology nurses was 16% (95% CI: 11%–22%) (Figure 8).

3.7. Factors Associated with Nurse Turnover. Four articles reported on the factors associated with turnover [30, 36, 42, 45]. The analysis of group differences demonstrated

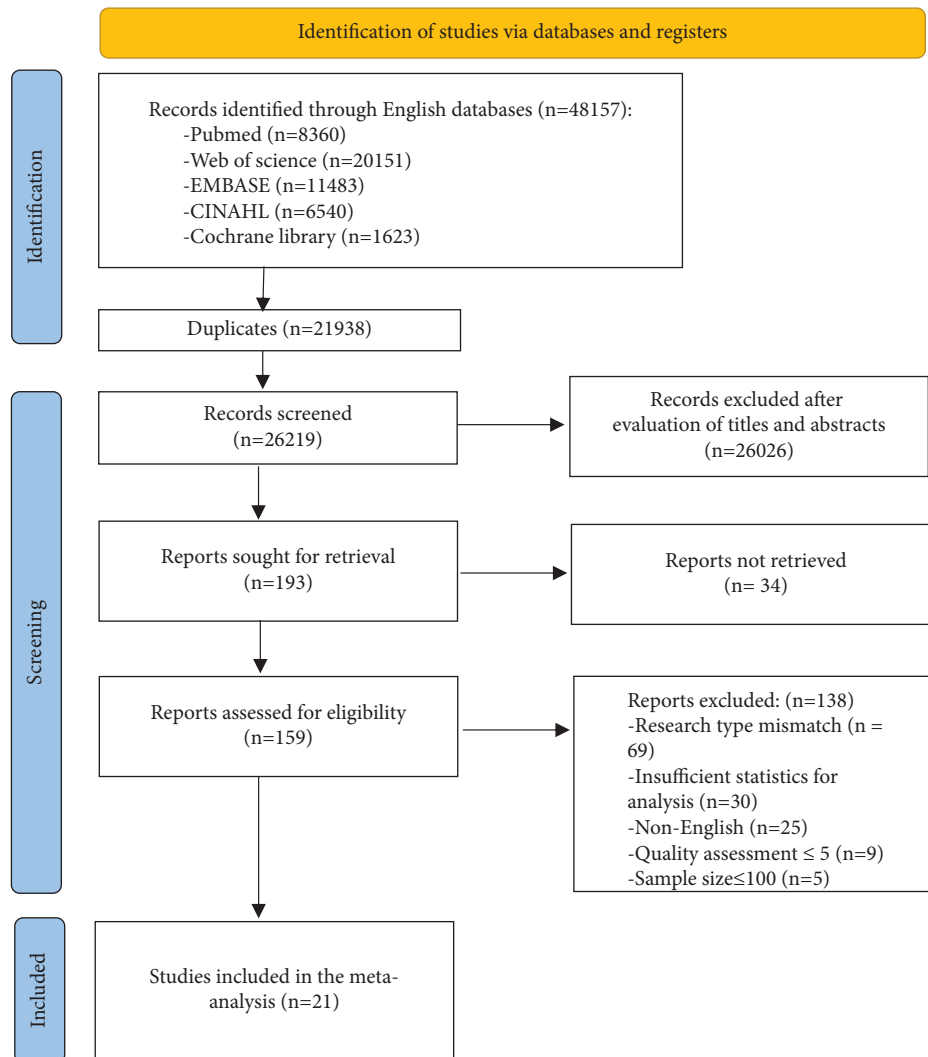

FIGURE 1: Flow diagram of study selection.

that the main factors included sex, labour unions, hospital size, work environment satisfaction, and job content satisfaction (Table 4). Specifically, nurses who were not members of trade unions (HR = 0.62, 95% CI: 0.51–0.77), worked in smaller hospitals (HR = 2.99, 95% CI: 2.89–3.10), were dissatisfied with their work environment (HR = 2.12, 95% CI: 1.40–3.23), or were dissatisfied with their work content (HR = 1.76, 95% CI: 1.21–2.55) were more likely to leave.

4. Discussion

Nurse turnover is an important issue that has attracted widespread attention from health care institutions worldwide. The World Health Organization has called for increased investment in human resources for nurses and advocates for policy attention and support through education, training, regulation, and employment systems [47]. Although the reported worldwide nurse turnover rates are inconsistent, higher nurse turnover rates will undoubtedly have a serious negative impact on the health care system, not

only causing greater economic burdens for medical institutions but also potentially having adverse effects on the allocation of nursing human resources, nurses' job satisfaction, and patients' health outcomes [48]. Consequently, this study represents a leading meta-analysis that provides a comprehensive estimate of the prevalence of nursing turnover from a global perspective.

4.1. Combined Prevalence of Nurses' Turnover. This study synthesizes results from 21 studies published between 2003 and 2023, involving 213,314 nurses from 14 countries. It found that nurses' turnover rates range from 8% to 36.6%, with a global combined rate of 16% (95% CI: 14%–17%). These data are similar to the 18% nurse turnover rate reported in 2024 [49]. According to other studies, the turnover rate of nurses is generally greater than that of other professionals in the health care field [50] thus indicating that the issue of staff turnover may be more pronounced in the nursing industry. The high overall prevalence rate once again underscores that nurses' turnover rate is a concern

warranting attention, with an urgent need for additional efforts to mitigate attrition in this workforce. However, due to variations in the definitions and measurement methods of nurse turnover rates among the studies in this meta-analysis, future research requires a unified definition and standardized measurement approach to more accurately assess and compare nurse turnover rates. Moreover, given that differences in health care systems, employment settings, cultural contexts, and professional standards across countries could affect the outcomes, significant heterogeneity may exist in the pooled results. Therefore, the combined prevalence estimates should be interpreted with caution. Furthermore, identifying the factors that could influence the turnover rate among nurses is also a critical issue.

Thus, this study conducted subgroup analyses to investigate the sources of the observed high heterogeneity in differences.

4.2. Geographical Region. This meta-analysis showed that the turnover rate of nurses in Asia (19%) was higher than in North America (15%), which may be attributed to different economic and cultural systems, as well as the management and operation modes of hospitals. Economically developed areas often offer more employment options, and nurses may find jobs with higher pay, better working conditions, or more prospects. Moreover, the lower nurse turnover rate in North America may be due to its health care systems placing greater emphasis on this issue, as evidenced by more extensive research conducted there. Another major reason may be related to the shortage of nurses in Asia. With respect to the global population, Asia ranks first and its nurse-patient ratio is seriously unbalanced. A survey demonstrated that the density of nurses in Asia is lower than the global

density [51], and a shortage of nurses directly increases the workload of working nurses and negatively affects their job satisfaction, thus increasing the possibility of nurse turnover [52, 53]. In contrast, the limited research on nurse turnover in Africa (54.4%) suggests less attention to the issue in these regions. More studies in the future could help refine these estimates globally.

4.3. Time of Publication and Study Start Time. The original studies that were included in this meta-analysis were published between 2003 and 2023. Subgroup analysis demonstrated that the global combined nurse turnover rate from 2015 to 2023 was lower than that from 2003 to 2014. Even for subgroup analysis based on study start time, the global combined nurse turnover rate between 2009 and 2019 was significantly lower than that between 2000 and 2008. The abovementioned studies show that the turnover rate of nurses in the 14 countries that were included in this study has exhibited a declining trend in recent years. This trend aligns with the World Health Organization's repeated emphasis on the importance of nurses, advocating the need to unleash their true potential and ensure that they have the resources and support to meet global health needs [3].

Considering that numerous studies have shown that nurse turnover significantly impacts hospital budgets and health care expenditure costs [43, 48], a growing number of countries worldwide are seeking to maintain the long-term stability of the nurse workforce by reducing nurse turnover. On the other hand, the education and professional skill levels of nurses have notably increased over the past two decades, leading to an enhanced sense of professional identity, which has been identified as one of the main factors in the

Obstetrics and gynecology	4	16	0.11	0.22	86.1	<0.001	

reduction of turnover rates [54, 55]. Simultaneously, governments and health systems have become increasingly aware of the vital role of nurses in improving patient health outcomes; thus, they have introduced policies and systems to actively improve the practice environment of nurses and improve their treatment and satisfaction [53, 56].

4.4. Work Department. Subgroup analysis demonstrated that the turnover rate was 23% for nurses working in ICUs and 16% for nurses working in obstetrics and gynecology departments. Nurses working in ICUs and obstetrics and departments have heavy workloads and long working hours; moreover, they frequently work overtime, are in a state of

FIGURE 5: According to the region, the turnover rate of nurses.

stress for a long period of time, and bear a considerable psychological burden. Studies have shown that nurses working in ICUs have high levels of stress, dissatisfaction, and job burnout [57, 58], and these factors are the main causes of nurse turnover [59]. These results suggest that nursing managers should prioritize the job satisfaction and physical and mental health of nurses in ICUs and obstetrics and gynecology departments. Appropriate actions, such as reasonable scheduling and increasing staffing, should be taken to reduce turnover rates in these areas.

4.5. Factors Associated with Turnover. Some studies have demonstrated that nurses who were not union members, who worked in smaller hospitals, and who were dissatisfied with the work environment and content were more inclined to depart.

Firstly, hospitals lacking union support may fall short in protecting employee rights, benefits, the work environment, and career development, all of which could lead to higher nurse turnover rates. Additionally, smaller hospitals often experience limitations in offering career development opportunities, creating a positive work environment, and allocating resources. These limitations may include limited

advancement paths, fewer professional training resources, lower social recognition, and greater job stress. These factors collectively may lead nurses to feel constrained in their professional growth, thereby motivating them to seek healthcare institutions that offer broader career prospects and superior working conditions. Research by Park and Ko supports this viewpoint, thus indicating that nurses particularly value opportunities for professional development and the quality of the work environment when evaluating potential job opportunities [42]. Therefore, to attract and retain nursing talent, small hospitals need to improve these critical factors; for instance, they can establish clear career development plans, offer regular professional training, improve working conditions, increase resource allocation, and enhance social recognition of nursing work. Through these measures, small hospitals can create an environment more conducive to nurses' professional growth and personal development.

Moreover, nurse turnover and lower job satisfaction are closely related, which supports the findings of Li et al. [60]; specifically, nurses want to have a cohesive, supportive, and independent practice environment. Hence, it is imperative for hospital managers to establish a practice atmosphere that fosters a cohesive team and supportive management.

FIGURE 6: According to the publication time, the turnover rate of nurses.

Finally, it would be more appropriate to be conservative in interpreting turnover-related factors because these meta-analyses are based on a limited number of studies. However, these findings provide important insights for future studies. These factors may greatly affect nurses' resignation, thus motivating researchers to conduct relevant large sample experiments in the future.

Obviously, nurse turnover is also influenced by other factors. Jones et al. categorized the reasons for leaving into internal and external factors. Internal reasons primarily include seeking opportunities for career development and advancement, job burnout, a tense work environment, and a lack of good leadership and management. External reasons mainly include nurses pursuing better compensation and benefits, experiencing high job stress, and having inadequate staffing [61]. Lee categorized the main reasons for nurse turnover into personal, hospital, and profession-specific factors. Among personal factors, the turnover rate among men is greater than that among women, which is a result that may partly be attributed to gender imbalance because the nursing profession is still predominantly occupied by women. Additionally, the education level also plays a significant role in

personal factors, as nurses with higher education may have greater capabilities to identify and access information about employment opportunities that are available in the current job market, thus resulting in better career planning. In addition to organizational factors within hospitals, career prospects, autonomy, social esteem, and interpersonal relationships (the satisfaction derived from the profession itself) are also factors affecting nurse turnover [35, 36].

Hayes et al. conducted a detailed analysis of the factors influencing nurse turnover and categorized them into three main areas: organizational factors, personal factors, and factors related to career development and economics. Among the organizational factors, four key points were emphasized: high workload intensity, ongoing stress and burnout, inadequate leadership abilities of managers, lack of empowerment, and high levels of role ambiguity and role conflict are all associated with higher nurse turnover rates. In terms of personal factors, an inverse relationship was reported between age, nurses with family responsibilities (e.g., dependent children or relatives), years of nursing experience, length of time in the position, and likelihood of leaving. Finally, in terms of career development and economic

FIGURE 7: According to the investigation start time, the turnover rate of nurses.

FIGURE 8: According to department, the turnover rate of nurses.

factors, nurses may choose to leave their current positions if they perceive better career development opportunities and compensation benefits that are available elsewhere [62]. To

reduce the turnover rate of nurses, health care institutions need to comprehensively consider these factors and take appropriate measures to address them.

TABLE 4: Meta-analysis of risk factors associated with nurse turnover.

Associated factors	Studies (<i>n</i>)	HR	Lower limit	Upper limit	<i>I</i> ² (%)	<i>P</i> for heterogeneity
Female (ref: male)	2	0.91	0.51	1.62	90.5	0.001
Labour union (no)	2	0.62	0.51	0.77	0.00	0.561
Hospital size (vs. large)						
Small	2	2.99	2.89	3.10	0.00	0.743
Medium	2	1.63	1.59	1.68	0.00	0.941
Workplace dissatisfaction (vs. satisfied or neutral)	3	2.12	1.40	3.23	68.9	0.040
Work content dissatisfaction (vs. satisfied or neutral)	2	1.76	1.21	2.55	50.6	0.155

4.6. Strengths and Limitations. Overall, the study conducted a comprehensive search of the relevant global literature to minimize the risk of omitting studies due to selection bias. Furthermore, through the use of rigorous methodological procedures and statistical analysis, data were collected and aggregated from 213,314 nurses from 14 countries, thus providing a scientific basis for policy makers worldwide who want to address employment stability in the nursing industry. Furthermore, both sensitivity and subgroup analyses were conducted to examine the potential sources of heterogeneity to enhance the rigor and reliability of the study.

In interpreting and applying the findings of this study, certain limitations must be considered. First, to utilize more accurate turnover rate data, certain studies were excluded because they only reported turnover rate, without providing the total employee number or the specific count of individuals who had left. This exclusion may have slightly influenced the study outcomes. Second, there was no clear, consistent definition of “turnover” in the included studies, which potentially led to the possibility of slight bias in the study findings. Moreover, due to the limited information presented by the original studies, there were insufficient data to explore the reasons and factors influencing turnover in this study. Finally, since the majority of the included studies were written in English, interpretations of the research findings should be approached with caution.

Therefore, future studies should include more detailed information on occupation-related, demographic, and family-social aspects, especially regarding the turnover rate of nurses working in different departments with different academic qualifications, ages, marital statuses, and durations of employment, which will be helpful for in-depth analysis of related factors. In addition, when experts and scholars evaluate nurse turnover, there should be a clearer definition of voluntary resignation and dismissal by medical institutions, which will facilitate a more comprehensive comparison. Given that there are few research articles on the nurse turnover rate in various countries that mainly focus on nurses’ turnover intentions, this study suggests that research on groups of nurses who actually leave their positions in the future should be increased. Only by truly understanding the factors influencing turnover in nurses who have left their positions can more accurate and more specific intervention measures or more reasonable policies and systems be formulated to reduce the turnover of nurses.

5. Conclusion

This study analysed existing published studies related to nurse turnover worldwide and demonstrated that the global nurse turnover rate was approximately 16%, thus implying an urgent need for efforts to reduce nurse turnover. High nurse turnover rates were observed in Asia (19%), ICUs (23%), and obstetrics and gynecology departments (16%). This emphasizes the need for health policy makers and nursing managers, particularly in Asia, to focus on reducing turnover in ICU and obstetrics and gynecology settings. The findings of this study underscore the urgent need for future intervention research aimed at reducing turnover among nursing staff, thereby enhancing the quality of patient care. However, research on the turnover rates of this population is relatively new and limited in some continents; therefore, further studies are necessary to more accurately measure the prevalence among this group.

6. Implication for Nursing Management

The study result shows that approximately 16% of nurses have experienced turnover, indicating an urgent need for efforts to reduce turnover. It provides a more comprehensive and objective understanding of nurse turnover for health care policy makers, hospital managers, and nursing leaders. It is suggested that all medical and health institutions actively adopt relevant systems and supporting policies that can reduce the turnover of nurses and promote a more harmonious, healthy, and safe occupational environment for nurses to strengthen the stability and sustainable development capacity of the nurse workforce. To reduce the turnover rate among nurses, it is essential to consider a comprehensive approach that addresses various factors such as the work environment, compensation and benefits, career development, workload, and psychological stress. For instance, human resources should be allocated rationally to reduce nurses’ work stress and increase job satisfaction, adopting scheduling systems and work principles that promote nurses’ physical and mental health. Additionally, establishing an attractive hospital culture can enhance nurses’ sense of belonging and provide personalized, diverse career development opportunities, thereby improving their satisfaction with the professional environment. Furthermore, strengthening public education to increase awareness and understanding of nursing roles will enhance nurses’ professional identity and motivate them actively in their work.

Data Availability

The datasets supporting this meta-analysis are from previously reported studies and datasets, which have been cited. The processed data are available from the corresponding author upon request.

Additional Points

Implications for Nursing Management/Contribution of the Paper. The shortage of nurses and high turnover rates pose significant challenges for healthcare organizations worldwide. Future research on nurse attrition should incorporate more comprehensive occupation-related, demographic, and family-social information, particularly by examining attrition patterns among nurses in different departments, educational backgrounds, age groups, marital statuses, and years of experience. It is crucial to clearly differentiate between voluntary attrition and resignation to provide a solid foundation for healthcare policy makers, administrators, and care leaders in formulating relevant policies. This study has several implications for nursing management. For example, managers must prioritize nurse retention efforts by strategically planning human resources to ensure an adequate nursing workforce that can meet patient needs; moreover, they should offer career advancement opportunities and foster professional development while cultivating a strong team spirit and fostering a positive organizational culture to enhance nurses' sense of belongingness and loyalty. By stabilizing the nursing team through these measures, the quality of nursing services can be improved, thus ultimately leading to better patient care.

Conflicts of Interest

The authors declare that they have no conflicts of interest.

Authors' Contributions

All listed authors (Hui Ren, Pan Li, Yingchun Xue, Xin Yin, Wenhao Xin, and Hongyan Li) meet the authorship criteria and that all authors are in agreement with the content of the manuscript. All the authors substantially contributed to the (1) design of the study, (2) data extraction, data analysis and interpretation, (3) drafting of the article, and (4) approval of the final version for publication. The authors Hui Ren and Pan Li contributed equally to this work and should be considered co-first authors.

Acknowledgments

We would like to thank all of the authors for their help.

The aim was to explore why registered nurses (RNs) in Sweden choose to quit their jobs in hospitals, also in relation to experienced patient safety. Previous research has shown that nurse turnover, especially in hospital settings, is a serious challenge for society and health care globally. Insufficient staffing of RNs is linked to poorer patient outcomes and a general patient safety at risk. It is, therefore, important to continually explore how nurses describe their reasons for quitting their jobs. The study was conducted using a qualitative descriptive design, based on 11 semistructured interviews with RNs. The analysis generated four categories describing the results: Feeling that the profession is not valued; Psychological and physical symptoms related to work; An insufficient and unsupportive organization; and Unsatisfying leadership and teamwork. Specifically, the RNs participating in this study described a range of reasons for quitting, where the feeling of not being valued and treated as a respected and autonomous profession was a common thread throughout the results. RNs experienced that, overall, the insufficient work conditions, also resulting in lower patient safety, ultimately led to their decision to quit. The findings highlight the crucial need for employers to develop working conditions for RNs, to make sure that the profession is valued according to professional standards and provide the potential for autonomous nursing practice. To reduce nurse turnover, and instead attract and retain nurses, leadership and management in nursing need to be adjusted to meet the demands of a modern academic profession.

1. Introduction

From a global perspective, nurse turnover, which can be defined as employees choosing to leave an organization or workplace, has been a serious challenge for the healthcare sector for decades [1–3]. The healthcare sector has for long been pinpointed as struggling to recruit and retain nurses, even more so in the aftermath of the COVID-19 pandemic [4]. In Sweden, the national situation in acute care hospitals has recently been described by national authorities as alarming and unacceptable regarding patient safety, primarily due to the employers' inability to recruit and retain nurses [5].

The causes of nurse turnover have been studied extensively over the years. Vital aspects that might influence nurses' decision to remain in their workplace are aspects related to leadership and management, career options, organizational environment, and number of colleagues [6, 7]. Additionally, generational differences can play a role [6, 8]. Several of the causes identified in the studies as reasons for why nurses quit, for example, poor work environment, are deemed preventable [9].

Job satisfaction and a healthy work environment are central factors that have an impact on nurses' turnover intentions [10–14]. Qualitative studies have identified a link between a well-functioning work environment and the

quality of patient care involving nurses and nurse midwives [15, 16]. Quantitative research exhibits variations in the definitions of work environment and the source of patient safety ratings, whether derived from nurses or nursing indicators, studies consistently highlight a connection between nurses' work environments and a range of nursing outcomes. These encompass, but are not restricted to, missed care, post-discharge mortality risk, incidents of falls, medication errors, and occurrences of pressure ulcers [14, 17–19]. One central aspect of high-quality care is patient safety, which by definition is fundamental to delivering health care that is effective, safe, and person-centered, and also prevents and reduces risks [20]. The consequences of nurse turnover are not limited to serious economic values but also comprise the effect on staffing and on nurse—as well as patient outcomes [2, 21].

Despite a substantial amount of scientific research on the topic of nurse turnover, myths continue to flourish on why nurses choose to quit, risking meaningless or even counterproductive interventions by employers striving to turn the trend. Previous research has emphasized the need for further studies in this area to focus on equity and the wellbeing of nurses, and on the underlying mechanisms of nurse turnover [21, 22]. Moreover, it is suggested that effective strategies to enhance retention and raise healthcare standards may exhibit variability among hospitals. Accordingly, these intricacies should be considered when devising and implementing interventions targeted at improving nurse retention [6], where qualitative studies are posited to contribute significantly to a more profound understanding of the nuanced and underlying factors influencing nurse turnover. To our knowledge, few qualitative studies have focused on how registered nurses (RNs) in a retrospective perspective describe job satisfaction and patient safety in relation to having quit their jobs, e.g., nurse turnover. Therefore, in this study, we aimed to explore why RNs in Sweden choose to quit their jobs in hospitals, also in relation to patient safety.

2. Materials and Methods

2.1. Design. The study was conducted using a descriptive design with a qualitative approach.

2.2. Informants and Setting. Informants were purposefully recruited through a university hospital with approx. 900 beds, and one county hospital with approx. 160 beds, in two healthcare regions in Sweden. A list of 53 RNs, who had quit their jobs in either medical or surgical units during 2018, was obtained through the respective HR departments. Only RNs on permanent contracts were included. An information letter, including an informed consent form, was sent by regular mail to all the potential informants. The first author made contact by telephone to follow-up on any questions, and if the contacted person was interested in participating, a time for an interview was scheduled. Eleven RNs finally participated. The recruitment resulted in variation regarding age (range 26–63), gender (men and women participated),

and experience as RNs (range 4–34 years since graduation). Four informants held a postgraduate diploma in specialist nursing, with or without an additional one-year master's degree. One participant held a Ph.D.

2.3. Interviews and Procedure. Data were collected from March 2020 to February 2021, using a semistructured interview guide. At the beginning of the interview, the informants were asked to describe some background characteristics. Below are examples of the main questions in the interview.

- (i) How would you describe your job satisfaction as a RN in your former workplace?
- (ii) Can you describe why you experienced/did not experience job satisfaction?
- (iii) Could you describe what would have been important for you to feel job satisfaction?
- (iv) Some describe a relation between job satisfaction and patient safety; what are your thoughts about this—considering your former workplace?
- (v) What are the reasons that you chose to quit your former job?
- (vi) What would make you rethink and return to your former workplace?

Interviews were carried out online or by phone, were audio recorded, and transcribed verbatim including emotional expressions. The interviews ranged between 32 and 62 min.

2.4. Data Analysis. The interviews were analyzed using systematic text condensation inspired by the description by Malterud [23]. The text was read by the authors to identify the preliminary themes. Text units that were considered relevant to the aim were identified and sorted according to these themes. Then, code groups were generated by the first author. Thereafter, all authors were involved in the reformulating and reconstructing of the codes until a consensus was reached. The content in each code group was re-contextualized and, subsequently, synthesized into four categories, describing the results. Illustrative quotes were used to strengthen the credibility of the results.

2.5. Ethical Considerations. All informants had signed a written informed consent form and were asked if anything was unclear before the interview began. All were informed that participation was voluntary and that they could withdraw from participation at any time without an explanation or questions being asked. Informants were told that data would be handled with confidentiality and that data would be presented without exposing any of the informants in a way that could cause them to be identified. None of the informants withdrew from the study. Ethical approval was obtained from the Regional Ethical Review Board (Reg. no. 2016/111).

3. Results

The analysis resulted in four categories which describe the registered nurses' reasons for quitting their jobs in the hospitals, including aspects of patient safety, where it influenced the decision.

3.1. Feeling That the Profession Is Not Valued. The RNs experienced that the employer did not value formal competence, such as a higher academic degree and senior expertise, and that visible career options are lacking. They expressed a wish to develop professionally, but the only career path that was evident was becoming a ward manager, also described as the only way to achieve an increase in salary. The informants felt that the salary was too low in relation to their formal competence and experience, which was an important factor influencing their decision to quit.

RNs felt that their professional development had stagnated, and an increase in salary was seen as impossible to negotiate outside the annual salary evaluation. Informants felt that they were seen as a collective rather than individual professionals, and that individual skills and competencies were not valued. RNs expressed that the employer encompassed a dated view on their competencies, such as the typical skills related to academic degrees in general. Career positions and roles for nurses where the individual's competence was valued were experienced as rare. Academic career paths and roles were not evident, which they expressed should be apparent already upon entering the organization.

Easiest for managers that all [nurses] are the same, just go in and do their job and nothing more. Do not ask any questions or show any personal interest. [...] It is perceived as a problem in healthcare that nurses should preferably be streamlined. Everyone should be equal, be equally experienced, everyone should do the same. (Informant 10)

[...] it's as much about tradition and culture. So that's... it's going to take a very long time to adjust or change. But I think it's about changing one's view of what is the ultimate goal for a nurse simply. [...] Because that's the thing with, should we be seen as a bit, like just a name on the schedule, or should we be seen as a competent [professional], so. And that is, of course, you must not close your eyes to the fact that we all need to fill a gap for care to work, of course. We need to make sure that there are nurses in place, but then you need to create a tradition and culture that sees the importance of our core competence. (Informant 8)

3.2. Psychological and Physical Symptoms Related to Work. The overwhelming work situation with extreme stress was described as causing both physical and psychological symptoms, leading to an unbearable situation. Being physically tired but still not being able to relax, constant stress, and having a stomach in knots, the feeling that "I am going to die here," not being able to think, not being able to concentrate, experiencing cold sweat, a racing heart, and the

feeling of "enough is enough" – all contributed to making the decision to quit. The stress caused RNs to feel their head spinning with thoughts after getting home from work and made it difficult for them to regain energy. Knowing that the stress caused dangerous situations for the patients added to the feeling of unsatisfying work situation. The stress and the overall work environment were described as a risk factor for missed care, threatening patient safety.

[...] I couldn't think, I didn't know what... I didn't know the time, I could concentrate on... or I couldn't sleep, because I was working three shifts. (Informant 5)

And if I want to be at work then, maybe I am happier, have more energy and have more motivation to work, which then... My attitude toward my work affects the patients, because they see me at my job. If I'm angry, sad or happy, it probably shows in me and how I behave toward the patients. And if I then feel unmotivated and depressed or feel "oh God, what a job... I don't even want to be here," I might miss certain things that my patient says, for example, just because I think that... or in case I have my thoughts in another place, etcetera. So, there are so many different factors that come into play. So, I definitely think that if you are satisfied, there will be increased patient safety. I think, it will definitely be. (Informant 1)

3.3. An Insufficient and Unsupportive Organization. RNs felt that an organization in the workplace supporting nursing was lacking, making it tough to perform their duties according to the professional nursing standards. The working environment was described as important, both to ensure patient safety and as an overall important aspect of work satisfaction. Permanent and extensive understaffing, especially regarding RNs, was viewed as having a substantial impact on the decision to quit. Due to the extreme work overload, sometimes the informants could not see the patients they were supposed to care for during a whole shift and had to discuss patients during rounds that they had not even met themselves. RNs were aware that patients needed them and that they were very ill – not being able to attend to their needs caused stress and made them feel they were not doing a professional job. They had difficulties in finding the time to even go to the bathroom themselves. Having to supervise students continually, and at the same time feeling new in the profession, added to the general burden and stress. Feeling bad toward colleagues was experienced as disheartening. Newly recruited colleagues could leave the workplace within months, and some even chose to leave the profession within a year.

[...] if you think about patient safety in the care unit, it means that resources must be available so that you can do your job and have time to see the patients. I feel that, it's really the most important thing, organizationally speaking. That it improves... yes, you need to have staffing and you need to have time, so that you have time to see your patients. Among the worst shifts is where you don't have time to see patients. (Informant 12)

Situations when the RNs had to care for patients who were outsourced to other wards than the one intended were described as especially stressful, since they did not feel they possessed the adequate competence and experience regarding the specific condition for which the patient was getting treatment.

There were a lot of shifts where [...] you found your nursing colleagues in the medicine room crying, and I never thought I'd be a part of that. But I was involved. (Informant 1)

Informants described that the working hours and scheduling had played an important role in the decision to quit. Work schedules were described as lacking flexibility, and the employer was unwilling to consider individual needs when organizing the schedule. Especially working days, evenings, and nights in a mix—sometimes resulting in only a few hours of sleep before the next shift—was deemed especially draining. The inflexible schedules were viewed as something that could cause illness and made it impossible to have a social life outside of work and to manage family obligations.

[...] it was this shift, above all, that it was so very messy with day, evening, day, evening and then every other weekend. So that was probably the big thing. (Informant 14)

[...] so it's development opportunities, it's the salary issue, it's the working environment. Then I would say . . . part of this, which I have admittedly been a little bit into, but which I have reflected on a lot, is connected to this thing of working three shifts and doing a rotation. But it's really about flexibility, in terms of working hours. Because it is also the case that people find themselves in different situations in one's life during one's life cycle. (Informant 8)

3.4. Unsatisfying Leadership and Teamwork. The RNs described leadership as a crucial factor influencing their decision to quit. This was described in terms of collegial support from both senior colleagues and from managers. Informants felt abandoned when being the only one that others turned to for advice and support, while they had no support from senior colleagues themselves; instead, they were solely dependent on the hospital physician on-call. Managers did not offer support, and nursing assistants were sometimes the only ones in the team with a longer experience. This was described as unsatisfying, since assistants lack knowledge of the scope of practice for RNs. Clinical supervision in nursing and senior support from colleagues with a higher qualification was described as necessary, but nurse practitioners and RNs with specialist competence were viewed as being too busy to provide adequate support. Informants also acknowledged that managers find themselves in unbearable situations where they are aware of the shortcomings and the poor work environment. Managers were also described as absent, not taking responsibility, and blaming each other—problems that were addressed were met with no response.

I think there is a lack of support and guidance in that case. Because I think that regardless of whether you are in a very critical or stressful situation, and you have colleagues next to you who can support you, I think that you can feel satisfied after a work shift. But if you don't have that, I think there is a lot that is missing. Because several times, I even thought, "no, but this is not the profession I should have anymore." (Informant 1)

Nursing management was described as insufficient and lacking leadership that would have been required to create an attractive work environment. Managers were experienced as absent and lacking interest in patient safety and the situation of the employees. Informants experienced that managers did not adequately address the individual professionals' interests, neglecting to value competencies and promote lifelong learning. Negative feedback and a lack of positive feedback were deemed discouraging. RNs described that managers were often new in their positions and were changed frequently. Managers' formal qualifications were questioned when they expressed a lack of interest in academic merits—something that informants could experience as a reason for quitting after they had accomplished a higher degree themselves.

They may not be disinterested, but it is probably overshadowed by the fact that they have other problems, organizational problems. That the department should be staffed 24 hours, with the right professions, that . . . yes. I don't think they are completely disinterested, but they are not schooled in it either, since there were two non-academic nurses [managers] at the time. Or one was academic but had no interest in academia . . . (Informant 10)

And, of course, I can also turn to my assistant nurses. We had a lot of people who were experienced and had worked there for ten, fifteen years. But they are not familiar with this particular . . . in our profession and what we do; so, it felt like I was talking to a wall sometimes. And when you tried to contact the manager about these problems, it wasn't often that they were there either. Or they were in meetings, were busy with something completely different, and didn't have time. So, it was probably a big part of why I finally felt that "enough is enough." (Informant 1)

RNs also described that a hierarchical structure in the workplace, lacking team collaboration and including interprofessional relations, contributed to their decision to leave. Physicians could be unfriendly and unsupportive; also, other RNs could act hostile, for example, when a colleague had achieved a new formal qualification, such as a higher academic degree. The overall atmosphere could be negative and unsupportive. Physicians could demand to be formally titled, and RNs could be ignored when greeting them. Rude behavior from physicians toward RNs was experienced as diminishing, and nursing as a profession was viewed as having an overall low status in the organization. Male RNs were deemed to be less exposed to hostile behavior than female RNs. Moreover, informants thought that a lack of

informal socializing between physicians and RNs had a negative impact on the teamwork. They also experienced an overall inequality between professions in the hospital, namely, that physicians have a clearer career path than they themselves after professional achievements, including academic degrees.

I had a situation when I was fairly new and working nights, where I was scolded for even daring to ring the back-up on call doctor instead of the primary on call doctor. But I thought, he didn't take me seriously. And when you called the back-up on call doctor, there was still someone who listened to you straight away. And then we could still help the patient, but then you were scolded for doing it that way. (Informant 4)

4. Discussion

The results in this study comprise four categories: Feeling that the profession is not valued, Psychological and physical symptoms related to work, An insufficient and unsupportive organization, and Unsatisfying leadership and teamwork. RNs who have chosen to leave their jobs as registered nurses in an acute care hospital describe a range of reasons for doing so. There were various reasons including feeling overwhelmed, consequences related to stress; a lack of a patient safety culture; an overarching experience of being treated unfairly and not according to what would be expected based on qualifications; not having the prerequisites required to practice their profession; poor leadership; and a lack of a nursing organization and insufficient career options, together with dysfunctional interprofessional teamwork.

The results show that the RNs' work situation with experiences of extreme stress caused both psychological and physical symptoms, experienced as linked to threatened patient safety. This is consistent with previous research regarding RNs' experiences of round-the-clock care, and how constant stress might have a serious impact on health and well-being, underpinning the decision to leave the workplace [16], with the feeling that "enough is enough." RNs felt the stress, along with a lack of recovery and replenishment of new energy between work shifts, was a risk factor for missed nursing care, thus experienced as threatening patient safety. This missed nursing care, also described as care left undone [24, 25] or unfinished nursing care [26], has been associated with lower patient safety [19, 27]. Missed nursing care, apart from the consequences for the patients, is associated with absenteeism, job dissatisfaction [28–32], poor retention and staff morale, turnover intention of nursing staff [26], but most of all, a burden on patient safety [19, 33]. Identifying current and up-to-date research in line with the findings in this study, unsurprisingly, did not present a challenge. This can be seen as noteworthy, since the topic has been addressed for decades, pointing out basically the same challenges and consequences for both patient safety and nursing as a profession [34, 35]. This highlights the utmost importance that the, now, substantial scientific evidence on factors affecting work environment and nurse

turnover [10–14] should seriously be considered in national and international policy, and by decision-makers in healthcare at all levels.

A connecting thread running through the categories was that the RNs in this study did not experience that they were treated as a respected *profession* by their employer, but rather as a replaceable workforce with a modest professional value to the organization. This shed further light on aspects of how RNs can be understood in large organizations, such as hospitals, and underlying aspects of what needs to be taken into account in reforming such organizations in order to facilitate recruitment and retention of RNs.

Employers were described as comprising an outdated view on RNs, not corresponding to what would be expected regarding a profession. Few visible career options, besides positions in ward management, were offered; moreover, employers did not seem to value higher academic degrees. Expectations on professional development were not met; furthermore, the working conditions, including salaries, did not make the RN's feel valued. These results are congruent with previous research in Swedish contexts, indicating that employers might not seek out autonomous academically trained professionals when recruiting RNs, but rather a workforce that is primarily expected to act as independent medical assistants, valued for their practical skills and dedication [36]. The medical perspective has been dominant in healthcare for centuries; it is only in the past decades that it has been challenged by other more holistic approaches to health [37], such as nursing, which originates from a holistic, caring, and person-centered approach to health [38]. Perhaps partly explained by being a "new profession" [39], RNs have struggled to gain influence and power, both in health policy as well as in hospital organizations. Nursing is still commonly seen as subordinate to medicine by the society [40]. This perception is also reflected by the results in our study, describing unequal career options compared to physicians and unsatisfactory interprofessional teamwork, where RNs might experience derogatory behavior from physicians. *If* the profession is still seen as subordinate to physicians, both in the team and at the organizational level, it might come as no surprise that RNs experience treatment as disparaging, and that such experiences in the long-term contribute to their decision to quit.

Somewhat surprisingly, the RNs in this study did not specifically bring up the need for an overarching structure for nursing leadership, although deficient and incompetent management at the ward level was emphasized as a reason for quitting. The explanation for this remains unclear, given that the specific question on overarching organizational leadership structures was not addressed in the interviews. Rodríguez-Pérez et al. [40] have articulated a need for nurses to strengthen their influence and leadership by gaining positions in faculty, professional organizations, and in health policy. Leadership, in general, is a central reason for nurse turnover, described in this study as well as in a substantial number of previous research studies [6, 7]. Regardless of the fact that healthcare organizations are constantly changing, thus affecting the healthcare staff [41, 42], it is unclear to what extent the professionalization of nursing [39] has had an impact on

organization, and employers' core views on nursing as a profession. The introduction of new public management [43] in healthcare has also been pointed out as reducing professional governance and influence in general, conceivably making it even more difficult for new professions to strengthen their mandates in such organizations. In continuously slimming organizations such as acute hospitals, traditionally run by the dominating medical perspective [37], it is conceivable that nurses have not reflected upon, or been able to influence the organization enough to create a career structure, allowing the profession to grow and develop substantially, also beyond bedside nursing.

As pointed out in previous research [44], organizational change in healthcare is best received when staff experience the need and value for change, especially regarding better patient care. The experiences shared by the RNs in this study indicate that the organizations they worked in had not fully integrated the status and value of them as full professionals. Not all hospitals in Sweden, for example, have positions as Chief Nursing Officer/Chief Nurse Executive in the highest organizational level, neither a clear structure nor a formal regulation for nursing leadership that runs from "top to bottom." Organizational culture and quality of leadership, have been linked to the ability to recruit and retain nurses in hospitals [6]. The results of this study underscore that RNs need to take actions to ensure that the profession gains mandates required to develop the organizational structures, where skills and education can thrive and are valued.

The academic progression and academic degrees in nursing, constituting a fundament in claiming professional status, are evidently linked to better patient outcomes and lower mortality [45, 46]. The results in this study indicate that, regardless of the development of nursing in Sweden during the past decades, originally initiated by the Swedish Higher Education Reform of 1977 [47] where nursing was integrated into regular university education, the parallel development in the employers' views might not have occurred. Nurses claim to fill the criteria of a profession [39], but other professions and organizational structures might not agree with this –which might be a somewhat overlooked cause when it comes to research on nurse turnover [7, 9, 16]. The results in this study suggest that it is important that the profession shoulder the ongoing process to address the need for structural change in both academia and healthcare. This is needed to ensure that RNs not only see possibilities of a professional career in healthcare but are also allowed and expected to practice nursing at its highest standards. A healthcare organization, which allows nurses to provide safe and person-centered care in a structure, where RNs are expected to lead the profession in well-functioning interprofessional collaborations on all levels, likely increases the chances of both recruiting and retaining nurses for the long term.

5. Methodological Considerations

The interviews in this study were conducted during the early outbreaks of the COVID-19 pandemic. This might have had an impact on the possibility of recruiting informants due to the overall, extreme burden in healthcare at the time.

Nevertheless, the informants in this study focused on a work situation that made them quit their jobs, which took place before the pandemic. Therefore, we believe that the results are not impacted by the extraordinary situation during the pandemic. Moreover, there is a potential for recall bias given the two-year gap between the termination of employment and the interviews. However, this time lapse might have allowed the informants to share experiences that were more reflective and less influenced by immediate and intense emotions surrounding the decision to quit. Nevertheless, despite this temporal delay, the interviews were characterized by richness and detail.

A facilitating factor in recruitment was that interviews were conducted online through phone or digital meetings. Both men and women participated in the study; however, as expected, due to the gender distribution in nursing in general, there were fewer men than women. The authors, therefore, chose not to specify the exact numbers to protect the integrity of the informants. Trustworthiness was achieved by carefully describing the context, and by a transparent and reflective communication between the authors in the whole process. This study was carried out by three women, all registered nurses. All worked as senior lecturers, and two also worked part-time with nursing quality development projects in hospitals. The authors have broad experience of conducting research interviews, and from the qualitative analysis method applied in this study. Transferability to other settings seems possible, but it is up to the reader to decide [48]. The authors had no previous relationship with the informants, and the study followed the Standards for Reporting Qualitative Research (SRQR) [49].

6. Conclusion

The RNs in this study expressed various reasons leading them to the decision to quit their jobs. These experiences ranged from overwhelming feelings of lacking the practical and organizational prerequisites to practice nursing at a professional standard, to severe understaffing together with insufficient scheduling and low salaries. Additionally, the RNs expressed the feelings of being valued and treated as a subordinate profession, not being expected to have the same expectations on professional autonomy and career possibilities as other professions. The RNs experienced that the, overall, insufficient work conditions, including an experienced lack of patient safety in several dimensions, ultimately pushed them to quit their jobs. Hence, RNs expressed a wish and expectation to practice their profession according to professional standards, and to be treated like a self-governing profession in the team and organization – but ultimately, they realized they were only seen by the employer as a replaceable brick in the game.

6.1. Implications for Nursing Management. The findings underscore the vital necessity for nursing management to develop overall working conditions and a leadership structure for RNs to ensure that the profession feels valued according to the professional standards and requirements

for autonomous practice. Nursing management and leadership need to be adjusted to meet the expected demands of a modern academic profession and move away from a potential collective view of RNs. To reduce nurse turnover and, instead, attract and retain RNs, the organizations ought to encompass a view on RNs as individual professionals, who are expecting the same treatment and career options as traditional academically trained professions. Nevertheless, it is equally important to underscore that the pervasive changes required to alter the perception of nursing as a profession cannot be accomplished solely by individual nurses or nurse managers, regardless of their level. Such changes also need to be promoted and implemented at the political and societal level, both locally and internationally. Since the challenges of retaining nurses are not confined to local or national contexts but are observed internationally, it is crucial to consider the specific situation in each country, which may influence how these issues should be addressed.

Data Availability

The interview data used in this study are available in the Swedish language upon reasonable request from the first author.

Ethical Approval

Ethical approval was obtained from the Regional Ethical Review Board (Reg. no. 2016/111).

Conflicts of Interest

The authors declare that there are no conflicts of interest regarding the publication of this paper.

Acknowledgments

The authors would like to acknowledge the RNs, whose generosity in sharing their experiences made this study possible. The study was funded by the Disciplinary Domain of Medicine and Pharmacy, Uppsala University. Open Access funding enabled and organized by Bibsam 2023.

Background: The global aging population has raised concerns about the fair distribution of elderly care resources. China, as the largest developing country, has made efforts to address population aging challenges. However, equitable distribution of elderly care resources remains a concern. This study analyzed the spatial layout and accessibility of elderly care service facilities (ECSFs) in Xiamen City to improve resource allocation and enhance the elderly care system in China. The findings provide valuable insights for other developing countries and regions seeking to improve their own elderly care resource allocation.

Methods: Xiamen City was chosen as the research area due to its unique geographical location and advanced information technology infrastructure. The study examined the spatial distribution, accessibility, and equity of ECSFs. Using Python, point of interest (POI) data were collected and evaluated using the kernel density method and two-step floating catchment area method. Spatial autocorrelation analysis identified areas of aggregation and dispersion in ECSF accessibility.

Results: Xiamen currently has 660 ECSFs, including nursing homes, adult day care centers, home care agencies, and rural elderly care homes. The analysis revealed spatial disparities, with ECSFs clustering primarily in the central area of Xiamen Island. Significant differences in accessibility were found among the four types of ECSFs. Spatial autocorrelation analysis identified cold and hot spot areas, indicating variations in accessibility across regions.

Conclusion: Xiamen City has made progress in allocating elderly care resources and constructing service facilities. However, equity in resource allocation remains a concern. Areas with limited accessibility were identified, leading to unequal access to elderly care resources and timely physical care. To address these challenges, decision-making departments should consider increasing facilities, improving transportation, enhancing macro planning, and improving facility service quality and accessibility. These measures will optimize ECSF accessibility and promote equitable distribution of elderly care resources.

Keywords: elderly care service facilities; health equity; nursing; older adults; spatial accessibility

1. Introduction

In recent years, the global aging process has continued to deepen [1], especially after the outbreak of the COVID-19 pandemic, where the elderly population became a key focus of care due to their weakened immune systems [2]. As the country with the largest aging population in the developing world, the demand for medical care, rehabilitation, and

elderly care resources for the elderly in China continues to increase [3, 4]. Informal care is facing challenges such as inadequate care manpower and low care quality, while formal care has begun to receive special attention. Under tremendous pressure, the government has made many attempts and introduced a series of positive policies [5, 6], which has led to the golden period of elderly care service system construction [7]. The elderly care industry has

flourished, the types and numbers of elderly care service facilities (ECSFs) have started to surge, and market-oriented elderly care methods such as home care, institutional elderly care, and community elderly care have emerged one after another. However, it is worth noting that some studies have shown that there are still problems with the equity of elderly care resource allocation in China [8]. There is an obvious supply–demand mismatch, and even some existing facilities in developed regions do not meet the fair and reasonable planning requirements [9–12].

Due to the decline in physical functioning, the elderly population has reduced adaptive capacity to the environment and is more susceptible to the influence of external environmental factors [13–16]. Therefore, for elderly individuals living in areas with fair allocation of elderly resources and reasonable spatial distribution of ECSFs, it is easier for them to access the necessary elderly resources and receive timely physical care at ECSFs. This enables them to meet their basic life needs at a lower transportation cost, ensuring their physical and mental well-being and enhancing their quality of life [17].

Accessibility assessment is a key indicator for measuring the equity and rationality of spatial distribution [18–20], and it has been widely applied in evaluating the layout of public service facilities such as education, healthcare, parks, and green spaces [20]. It can reflect the ease or difficulty for the elderly population in accessing elderly care services.

Currently, there are many methods used by scholars for accessibility assessment in the field of elderly resource allocation, and the corresponding indicators are also diverse [21]. However, they mainly involve two analytical approaches: accessibility assessment based on opportunity accumulation and accessibility assessment based on spatial interaction. Accessibility assessment based on opportunity accumulation focuses on quantifying the amount of resources that facility points or residential points can access within a certain time threshold. Spatial interaction models are geographic methods derived from Newton's universal law of gravitation. Their advantage lies in their ability to utilize relevant data to elucidate the interaction between supply and demand of elderly resources and to analyze the impact of geographical accessibility on individual behavior while evaluating individual spatial accessibility. In summary, the accessibility assessment methods based on opportunity accumulation consider multiple factors such as transportation networks, distribution of service facilities, and population density. They delve deeper into the cumulative effects of resources and the consideration of temporal factors. However, the application of such spatial analysis methods in the field of elderly resource allocation is still relatively limited.

From the perspective of research content, there are still some limitations in the current studies on accessibility assessment of elderly resources. First, the research scale is not sufficiently refined. Existing studies often treat a city or a specific urban area as a whole, without delving into the specific accessibility of each residential cluster. This overlooks individual travel time and living range, which may lead to research conclusions that do not align with reality [22].

Second, the research areas mainly focus on the core urban areas or specific regions of a city, with fewer comprehensive assessments of accessibility across the entire city, neglecting to address the disparities between rural and urban areas. Furthermore, there are various types of ECSFs, but most studies do not classify them or only focus on the accessibility of a specific type of facility [23]. Lastly, existing research data often come from government official statistical yearbooks, which may lack detailed information and may not be promptly updated [24].

In summary, while the elderly care industry in China has been rapidly developing, it has also revealed issues such as unfair resource allocation and mismatched supply and demand. Faced with the dilemma of elderly individuals being unable to access care services equitably, there are currently some deficiencies in the methods and content of evaluating the accessibility of elderly care resources. Therefore, this study establishes the following research logic and objectives: First, by employing Python programming language, a web crawler program was developed to obtain the latest point of interest (POI) data on ECSFs in Xiamen City. These data include information such as name, category, coordinates, and classification. Second, using kernel density estimation, two-step floating catchment area (2SFCA) method, and spatial autocorrelation analysis, a comprehensive evaluation was conducted on the spatial accessibility and equity of various types of ECSFs in Xiamen, including nursing homes (NHs), adult day care centers (ADCs), rural health clinics (RHCs), and home care agencies (HCAs) (see Figure 1 for details).

The aim is to identify potential issues in the allocation of elderly care resources in Xiamen, expand the theoretical knowledge to address resource allocation problems, provide a basis for scientifically formulating resource allocation plans, rationalize the layout of elderly care service planning, enhance the quality of care for the elderly population, and improve the overall elderly care service system. Moreover, this study aims to provide valuable insights that can be applied to other cities in China as well as various developing countries and regions.

2. Methods

2.1. Research Site. Xiamen is located in the southeast of Fujian Province in East China (the specific location of Xiamen City can be seen in Figure 2, and the satellite image is shown in Figure 3(a)). As of 2021, Xiamen has six districts, including Siming, Huli, Jimei, Haicang, Tong'an, and Xiang'an, with 37 streets and eight towns (as shown in Figures 3(b) and 3(c)). The total area is 1700.61 square kilometers, with a permanent population of 5.28 million [25]. The total length of roads in the city (excluding natural village roads) is 2223.13 km, including 259.17 km of national roads, 240.4 km of provincial roads, 394.9 km of county roads, 657.4 km of township roads, and 671.27 km of village roads (as shown in Figure 3(d)).

As a developed city on the southeastern coast of China, Xiamen has a high level of economic development, a strong foundation for elderly care services, well-developed

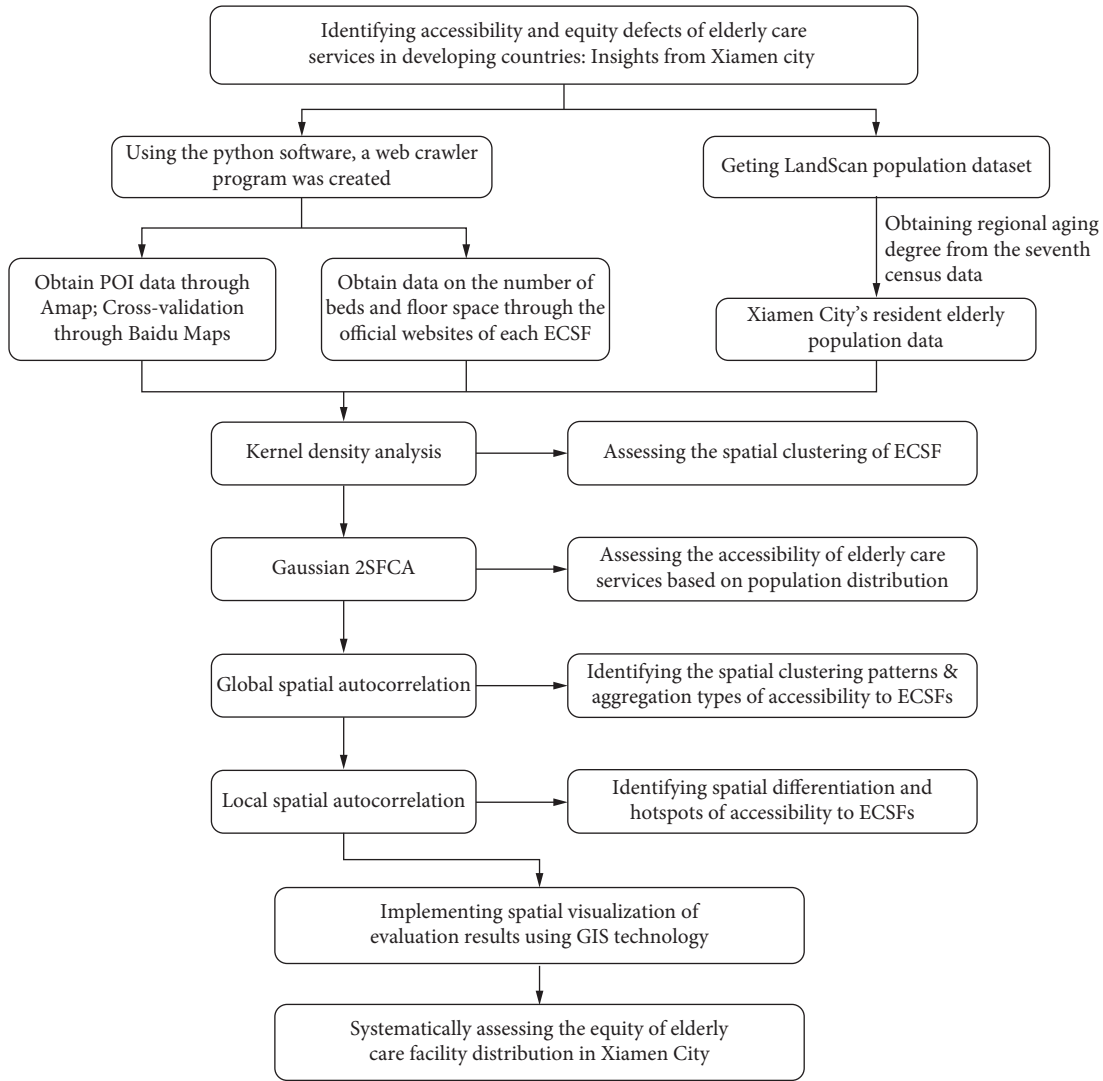

FIGURE 1: Research framework.

FIGURE 2: Research site.

information technology infrastructure, transparent access to various types of information, and easy accessibility. The city has set goals for future elderly care service system development: By 2025, a batch of urban convenient living circles with complete functions, smart and convenient services, and high-quality service and living harmony will be built, in accordance with the requirements of a “15-min living circle,”

to reduce the difficulty in obtaining elderly care services. At the same time, the city continues to focus on the equity of elderly care service access and aims to establish a sound elderly care service system based on home care, supported by the community, supplemented by institutions, and integrating medical and elderly care by 2035. This will expand elderly care services from specific populations to the general

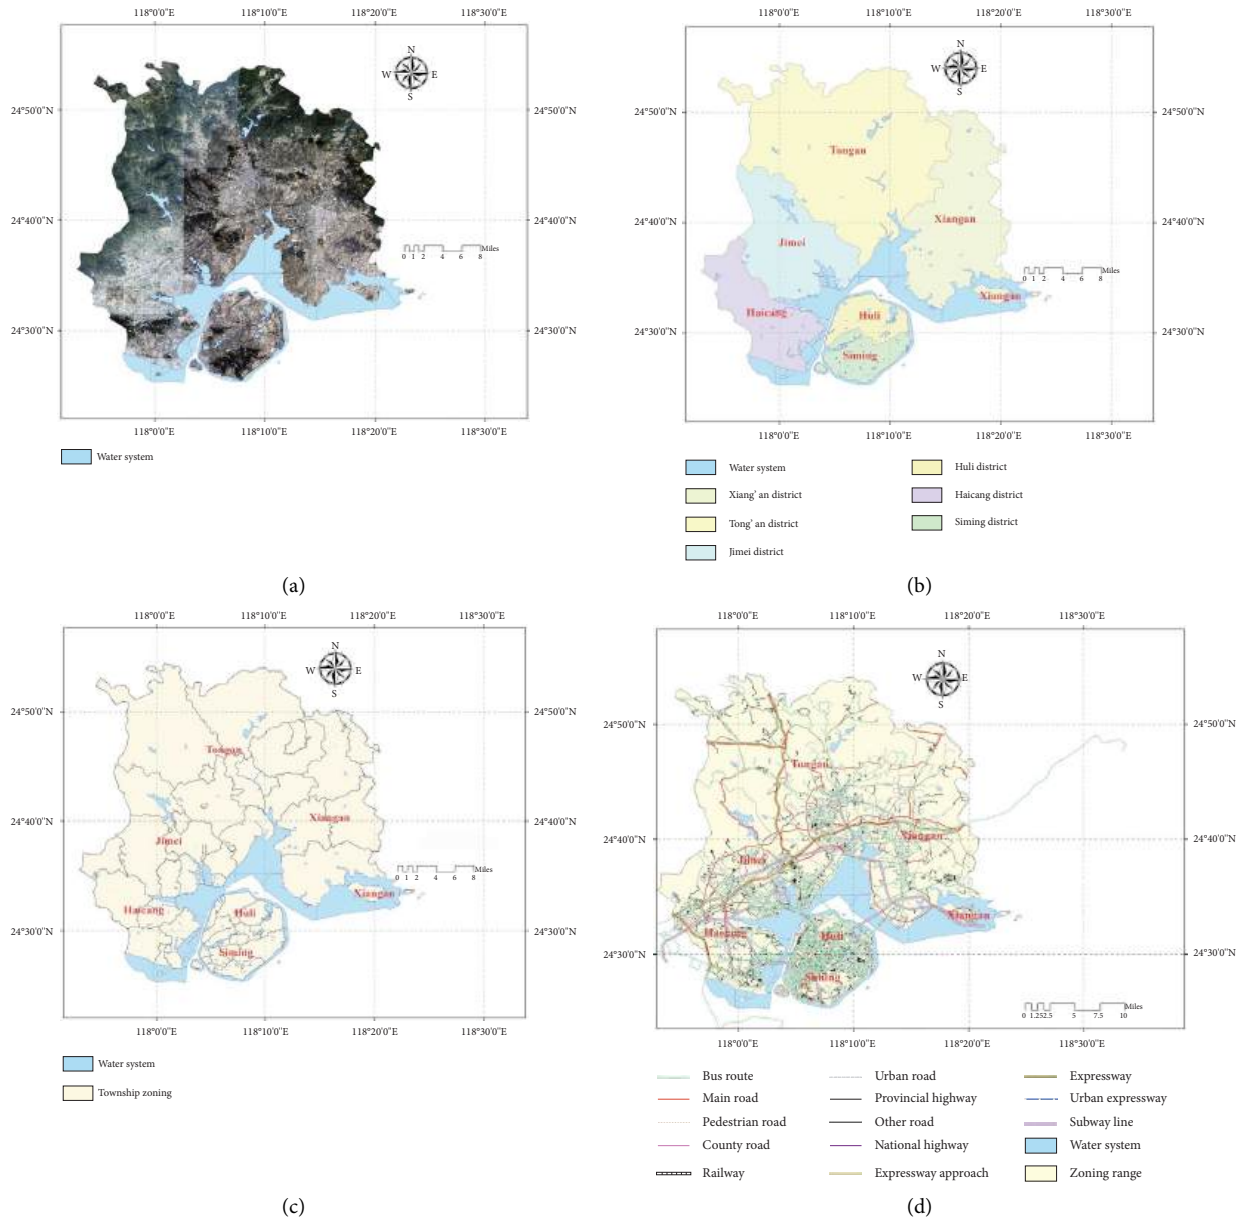

FIGURE 3: (a) The Xiamen satellite map, (b) the extent of administrative divisions in Xiamen, (c) the extent of street and township divisions in Xiamen, and (d) road traffic in Xiamen.

public, transform social welfare from “deficiency compensation” to “universal coverage,” and ultimately achieve a minimum of 40 senior care beds per thousand elderly people and a per capita land area for ECSFs of no less than 0.1 square meters in urban and rural areas [26]. As the global aging population increases, economic development and national economic strength continue to improve in China and other developing countries, and more and more cities will follow a development trajectory similar to Xiamen. Therefore, Xiamen City was selected as the research area for this study to clarify the equity of ECSF construction in developed Chinese cities and to provide experience and reference for other developing countries and regions.

2.2. Data Acquisition. According to the 15-min living circle construction criteria and the spatial layout planning of ECSFs in Xiamen City, this study classified the ECSFs into four categories: A (NHs that provide long-term centralized nursing services, with a service radius of 10–15 km), B (ADCs that provide day care services, with a service radius of 1–1.5 km), C (REHs that mainly serve rural residents, providing comprehensive elderly care services based on home care and community support, with a service radius of about 1 km), and D (HCAs that mainly serve urban residents, providing home-based services within 1 km). The specific service radius was determined based on the number of beds in each facility.

To conduct a scientific evaluation of the layout of ECSFs, it is necessary to analyze and study them in the context of geographic space. Traditional methods of data acquisition often rely on sources such as statistical yearbooks and registration data from civil affairs bureaus, utilizing methods such as surveys and door-to-door inquiries. However, these approaches are time-consuming and labor-intensive and may face challenges in obtaining data due to issues such as permissions. While secondary statistics from government or health departments may have higher reliability, they often lack detailed information on individual medical institutions due to access restrictions. Moreover, official secondary data are typically updated only once a year or even less frequently, leading to potential data lag. In the current context of various medical vertical portals and Internet mapping service providers, Internet data offer advantages such as large volume, timeliness, and low acquisition costs. Therefore, this study starts with Internet data and utilizes Python web scraping techniques and Internet open platforms to collect data related to elderly care facilities and the associated assessments.

Among the collected data, the information on elderly care facilities and road traffic POIs was collected in March 2023. The data on population aggregation points were collected at the end of 2021, and the estimation of the elderly population in each administrative region was based on the results of the seventh national population census of China.

The POI web crawler software used in this study was developed using Python 3.10. The road traffic data were sourced from Amap (<https://ditu.amap.com/>) and Baidu Maps (<https://map.baidu.com/>). The data on elderly care institutions were collected from the Xiamen Municipal Government's Convenience Platform (<https://www.ixiamen.org.cn/>) and various official websites of the care institutions, such as Xiangyu nursing home (<https://xiangyuciai.com/>) and HA nursing home (<https://www.hanursing.com/>). Python 3.10 was employed for statistical analysis, while ArcGIS 8.0 software was utilized for creating the statistical maps.

2.2.1. ECSF. This study utilizes the Amap Developer Platform and its Web development service module to search for POIs by developing a Python web crawler script. The script is designed to match the specified data request format in order to obtain POI data for elderly care institutions with geospatial information, including names, categories, coordinates, and classifications. To validate the results, cross-validation is performed using POI data obtained from Baidu Maps.

After the statistical classification of POI data, the number of beds and floor area data were obtained by querying the official websites of various ECSFs. Table 1 shows an example of obtaining data.

2.2.2. Demographic. In existing research on the quantification of accessibility and equity of ECSFs, population data from regional statistical yearbooks are often used as the demand-side data. The statistical scale is mostly at the level of administrative regions or streets, which can lead to

homogenization of the calculation results. To obtain more realistic results in accessibility calculations, this study narrowed the statistical scale and used population data within a 1 km * 1 km range as the demand scale for accessibility evaluation.

The population spatial distribution grid data of Xiamen City are sourced from the 2021 LandScan population dataset by Oak Ridge National Laboratory (<https://landscan.ornl.gov/>). These data provide community-level population distribution data worldwide, with a spatial resolution of 1 km × 1 km, sourced from the total amount of environmental data over a period of time. In this study, we used these data in combination with the elderly proportion in each administrative region in the seventh national census report (see Table 2) to estimate the number of elderly people in the study area.

2.3. Statistical Methods. In this study, a series of spatial statistical methods were employed to assess the fairness of elderly care facility distribution in Xiamen City. Specifically, we utilized the following methods: First, kernel density analysis was used to illustrate the spatial clustering patterns of different types of elderly care facilities. However, this method only displays the density quantity of facilities in space and does not reflect the actual relationship between the elderly population and the availability of care resources. Therefore, in this study, we employed the Gaussian 2SFCA (Ga2SFCA) method to delve deeper into the accessibility of various types of care institutions. Moreover, we conducted global spatial autocorrelation analysis and local spatial autocorrelation analysis to identify the spatial heterogeneity of elderly care facility accessibility in Xiamen City and pinpoint specific cold and hot spot areas. This comprehensive evaluation allowed this study to provide a more thorough assessment of the elderly care facilities in Xiamen. Here is a brief introduction to the specific statistical methods employed.

2.3.1. Kernel Density Analysis. Kernel density estimation is a nonparametric method used for spatial analysis of point elements. It estimates the density variation of point distributions using a moving unit and reveals the clustering patterns of point elements on a spatial scale, thus reflecting the accessibility of elderly resources [27]. The formula for calculating kernel density is given by the following equation:

$$\lambda_s = \sum_{i=1}^n \frac{1}{\pi r^2} \varphi\left(\frac{d_{is}}{r}\right), \quad (1)$$

where λ_s represents the kernel density value at grid s , r denotes the search radius, n indicates the total number of POI points, d_{is} represents the distance between POI points, and φ represents the weight.

2.3.2. Ga2SFCA. The 2SFCA method, as a mainstream accessibility evaluation method, has received widespread attention from scholars and has been introduced into research on elderly care resource allocation [28]; it can

comprehensively consider the capacity, distribution, type, distance, and travel mode of service facilities and is easy to be personalized designed.

The Ga2SFCA was proposed by Dai in 2010. He used a Gaussian function as the distance decay function $g(d_{ij})$ [29] within the 2SFCA search domain for the accessibility evaluation of medical facilities. The specific calculation method can be found in the following equation:

$$A_i = \sum_{j=1}^n \frac{S_j f(d_{ij})}{\sum_{k=1}^m D_k f(d_{kj})}, \quad (2)$$

where A_i represents the accessibility of demand point I to obtain pension services, d_{ij} represents the road network distance between supply point j and demand point I , d_{kj} represents the distance between supply point j and demand point k , and $D f(d_{ij})$ represents the distance decay function. It can also be further expressed as the following equation:

$$f(d_{ij}) = \begin{cases} g(d_{ij}), & d_{ij} \leq d_0 \\ 0, & d_{ij} > d_0 \end{cases}, \quad (3)$$

where $f(d_{ij})$ represents the distance decay function, d_{ij} represents the distance between the supply point j and the demand point i , d_0 represents the search range, and $g(d_{ij})$ represents the distance decay function within the search range d_0 . $g(d_{ij})$ is introduced as a modified calculation of the original 2SFCA method by introducing the decay function. In the original 2SFCA method, $g(d_{ij})$ is always a constant value of 1.

The proposed method differs from the original 2SFCA method in several aspects. First, this method enables a random exploration of the entire search space to seek the global optimum. In addition, it employs an adjustment of the search step length and direction, along with a sampling strategy using Gaussian distribution, to perform a more refined search in the neighborhood, aiming to find solutions that are closer to the local optimum. Second, it effectively deals with uncertainties and noise within the search space by employing an adaptive adjustment of the search step length and direction, as well as a sampling strategy using Gaussian distribution. This robustness enhances the reliability and stability of the algorithm when dealing with complex problems in the real world. Lastly, the Gaussian distance decay function exhibits an increasing decay rate with distance, initially accelerating and then decelerating. This pattern is analogous to people's expectations in real-life decision-making processes regarding the selection of

elderly care facilities. Therefore, it can simulate real decision-making states more realistically [30].

The calculation expression is as follows:

$$g(d_{ij}) = \frac{e^{-(1/2)} \times (d_{ij}/d_0)^2 - e^{-(1/2)}}{1 - e^{-(1/2)}}, \quad d_{ij} \leq d_0. \quad (4)$$

2.3.3. Spatial Autocorrelation. Spatial autocorrelation is commonly used to explore the presence of statistical correlation between data or variables in space or to investigate the potential mutual influence among several indicators. The research theory inherits from the first law of geography proposed by the Swiss geographer Waldo Tobler, i.e., everything is related to everything else, but near things are more related than distant things [31]. Spatial autocorrelation can reveal the distribution and pattern characteristics of data in space, such as exploring the aggregation and dispersion of data and identifying the hot and cold spots of data distribution. Therefore, it is often used to study the distribution of related indicators of public service facilities. In this study, the Global Moran's I and Getis-Ord General G indices were used to analyze the spatial distribution characteristics of the accessibility of ECSFs, and the Local Indicator of Spatial Autocorrelation (LISA) and Getis-Ord G_i^* tool were used to identify the areas of aggregation and dispersion of data.

2.3.3.1. Global Spatial Autocorrelation. Global Moran's I reflects the overall spatial autocorrelation of the study area and is used to determine whether there is spatial autocorrelation in the research object as a whole. It is a spatial autocorrelation statistic for the entire study area. The Getis-Ord General G method is used to preliminarily determine the clustering type.

The Global Moran's I method of global spatial autocorrelation is given in the following equation:

$$I = \frac{n}{S_0} \times \frac{\sum_{i=1}^n \sum_{j=1}^n w_{ij} (y_i - \bar{y})(y_j - \bar{y})}{\sum_{i=1}^n (y_i - \bar{y})^2}, \quad S_0 = \sum_{i=1}^n \sum_{j=1}^n w_{ij}. \quad (5)$$

The Getis-Ord General G method of global spatial autocorrelation is given in the following equation:

$$G = \frac{\sum_{i=1}^n \sum_{j=1}^n W_{i,j} x_i x_j}{\sum_{i=1}^n \sum_{j=1}^n x_i x_j}, \quad j \neq i, \quad (6)$$

where $y_{i(j)}$ represents the accessibility calculation value obtained from residential area i (j) in this study; y represents the mean value of all research area data, which is the mean accessibility value of all residential areas in this study; n represents the number of residential areas; and W represents the spatial weight matrix [32].

2.3.3.2. Local Spatial Autocorrelation. Global spatial autocorrelation statistics indicate the presence of clustering, while local spatial autocorrelation indicates the location and type of spatial association. To further study the distribution pattern of the spatial accessibility scores of ECSFs, this study used the LISA analysis method to identify local clusters of accessibility. Due to the heterogeneity of space, there may be different aggregation states in different geographical locations. LISA [33] is suitable for studying the heterogeneity characteristics of the clustering of ECSF accessibility. It calculates local indicators for each observation in the dataset and identifies four types of spatial association: (a) high–high (HH): locations with high attribute values surrounded by other locations with high attribute values. This indicates spatial clusters of similar values; (b) low–low (LL): locations with low attribute values surrounded by other locations with low attribute values. This also indicates spatial clusters of similar values; (c) high–low (HL): locations with high attribute values surrounded by other locations with low attribute values. This indicates spatial outliers or anomalies; and (d) low–high (LH): locations with low attribute values surrounded by other locations with high attribute values. This also indicates spatial outliers or anomalies.

The Getis–Ord G_i^* tool is suitable for hot spot analysis and can analyze the distribution of cold and hot spots of accessibility. The interpretation of the results is as follows: (a) positive G_i^* values: locations with positive G_i^* scores have high attribute values and are surrounded by other locations with high attribute values. This indicates statistically significant hot spots or areas of high clustering; (b) negative G_i^* values: locations with negative G_i^* scores have low attribute values and are surrounded by other locations with low attribute values. This indicates statistically significant cold spots or areas of low clustering; and (c) Z-scores close to zero: locations with Z-scores close to zero have attribute values similar to their neighbors, indicating no significant spatial clustering or dispersion.

The calculation expression is as follows.

The LISA method of local spatial autocorrelation is given in the following equation:

$$I_i = \frac{n(x_i - \bar{x})\sum_{i=1}^n \sum_{j=1}^n w_{i,j}(x_i - \bar{x})}{\sum_{i=1}^n (x_i - \bar{x})^2} \quad (7)$$

The Getis–Ord G_i^* method of local spatial autocorrelation is given in the following equation:

$$G_i^* = \frac{\sum_{j=1}^n W_{i,j}x_j - \bar{X}\sum_{j=1}^n w_{i,j}}{S\sqrt{\left[\left(n\sum_{j=1}^n w_i^2 - \left(\sum_{j=1}^n W_{i,j}\right)^2\right)/n - 1\right]}} \quad (8)$$

where x_i and x_j are attribute values for features i and j ; $w_{i,j}$ is the spatial weight between feature i and feature j ; and n is the number of features in the dataset. When the G_i^* statistic is higher than the mathematical expectation and passes the hypothesis test, it is a hot spot; otherwise, it is a cold spot [32].

3. Results

3.1. Description. As of March 2023, there are 660 ECSFs in operation in Xiamen City, including 41 NHs and 44 ADCs, mainly located on Xiamen Island in the Huli and Siming districts. There are 441 HCAs, mainly distributed in population clusters on Xiamen Island and near the sea. There are also 134 REHs, mainly distributed in the Tong'an District. The specific distribution is shown in Figure 4(a). The Siming District has the highest concentration of elderly population, while the Xiang'an District has the lowest, and overall, the distribution shows radiation decay from the island to the outside, as shown in Figure 4(b).

3.2. Kernel Density Analysis. Kernel density analysis can show the spatial clustering of the distribution of ECSFs based on their quantity. The analysis results are shown in Figure 5, which reveals a serious clustering in the spatial distribution of various types of ECSFs in Xiamen City. NHs, which provide long-term care, are mainly concentrated in the Siming and Huli districts, with some clustering in the population clusters of Jimei and Tong'an, and lower clustering in other areas. ADCs, which mainly provide general care and companionship services, are mainly concentrated in the southwest of Xiamen Island. HCAs mainly provide on-site safety, daily living, and basic medical services to elderly people in surrounding communities, with main clusters in the Siming and Huli districts on Xiamen Island, but with the broadest coverage among all ECSFs. REHs mainly serve rural elderly people and provide comprehensive day care services such as daytime rest and leisure activities. They are mainly located outside Xiamen Island, with main clusters in the Tong'an and Jimei districts and few distributions on Xiamen Island.

According to the results of the kernel density analysis, the spatial distribution of existing ECSFs in Xiamen City is uneven, with most of them showing a clustering state centered on Xiamen Island. However, as kernel density analysis can only display the density quantity of various facilities in space, it cannot reflect the true relationship between the elderly population and the availability of elderly care resources. Therefore, it is necessary to use the Ga2SFCA method to further explore the accessibility of various ECSFs.

3.3. Accessibility Analysis. In order to fully consider the factor of aging population and further measure its true relationship with the availability of elderly care resources, this study used the Gaussian two-step mobile search method to evaluate the accessibility of ECSFs in Xiamen City.

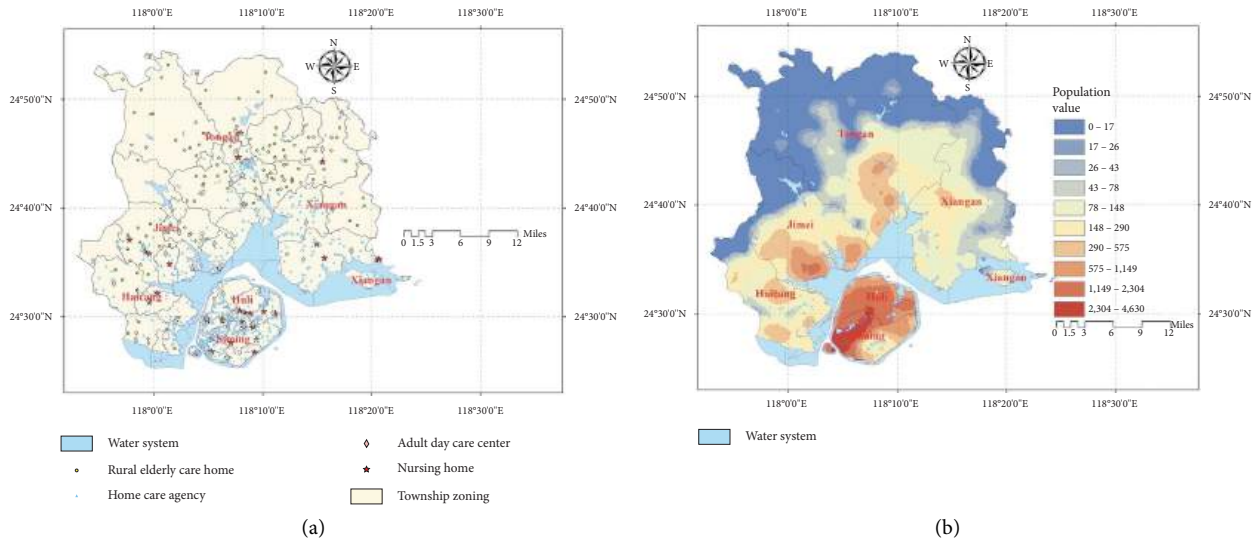

FIGURE 4: (a) The distribution of 660 ECSFs and (b) the distribution of the elderly population in Xiamen.

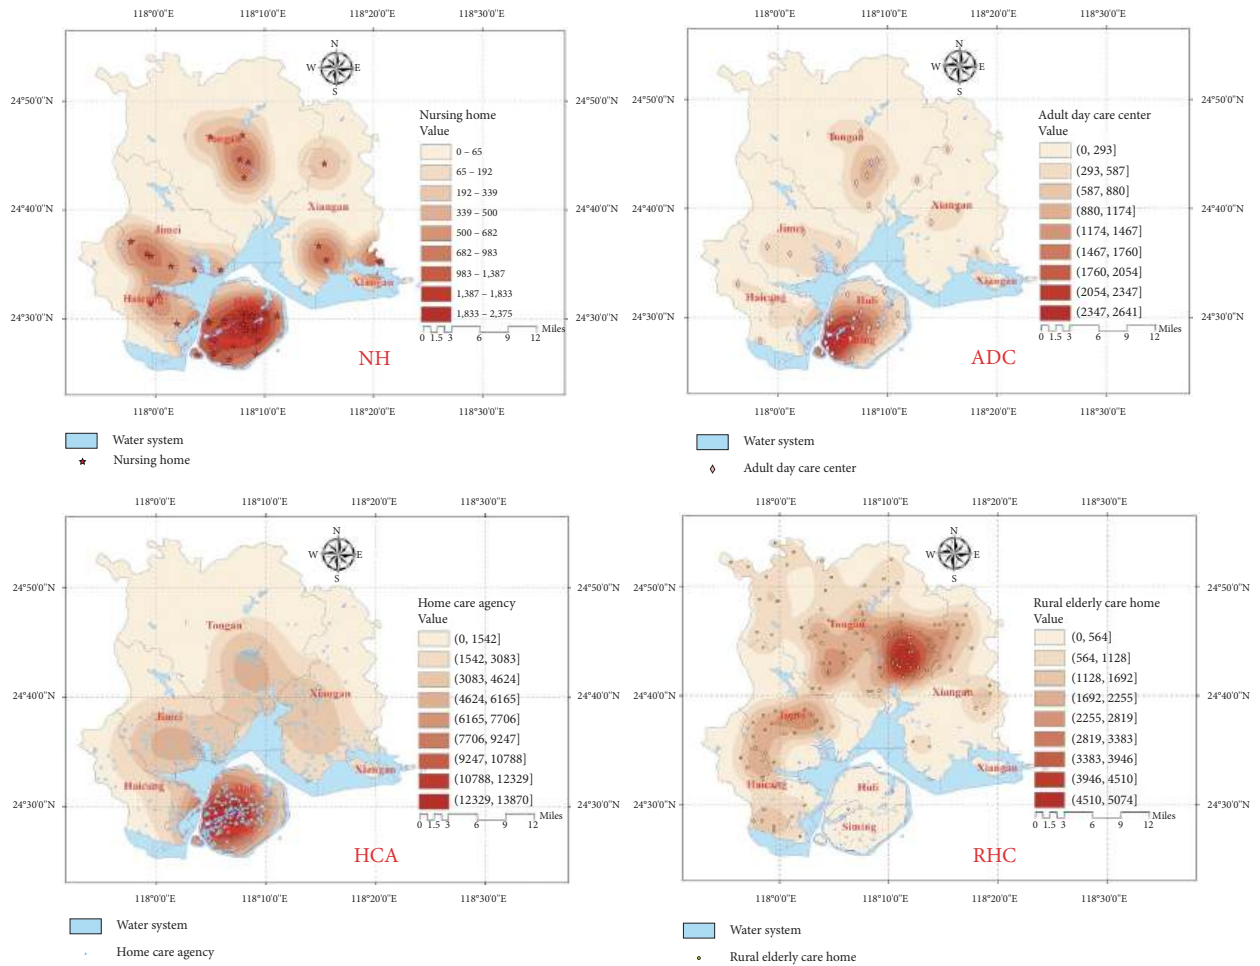

FIGURE 5: Result of kernel density analysis of ECSFs.

Considering that Xiamen Island (Siming and Huli districts) and the surrounding areas (Haicang, Jimei, Tong'an, and Xiang'an districts) are separated by sea, this study set up

path barriers around Xiamen Island. The detailed accessibility distribution results of ECSFs in Xiamen City were obtained and processed by Kriging interpolation, as shown

in Figure 6. The high accessibility areas of NHs are mainly located in the midlatitude areas of Xiamen Island and Haicang District, while the low accessibility areas are mainly located in the northeast and northwest of Xiamen City. The high accessibility areas of ADCs are mainly located in the northwest, while the low accessibility areas are mainly located in the eastern areas. The low-value areas are mainly located on Xiamen Island, where HCAs are mainly clustered. The high-value areas of REHs are mainly located at the boundaries of Jimei, Tong'an, and Xiang'an districts, while the low-value areas are mainly located in the population clusters in the south of Xiamen Island and Tong'an District.

3.4. Global Spatial Autocorrelation. From the analysis of global spatial autocorrelation, it can be seen that the accessibility of the four types of ECSFs all show a significant clustering distribution state in space, with the REH showing the strongest positive correlation (Moran's $I=0.777853$; observed General $G=0.005048$) and the ADC showing the lowest positive correlation (Moran's $I=0.299089$; observed General $G=0.009919$). Details can be found in Table 3.

3.5. Local Spatial Autocorrelation Analysis. Based on the analysis of global spatial autocorrelation, this study used local spatial autocorrelation analysis to identify specific discrete and clustered areas in space. The results are as follows. The LISA map shows that the high-high clustering area of NHs in Xiamen City mainly appears in the central part of Xiamen Island and Haicang District, while the low-low clustering area is densely distributed in the midlatitude areas of Xiamen City. The high-high clustering area of elder care centers appears in Xiang'an and Tong'an districts, with large surrounding areas of low-high clustering. The high-high clustering area of HCAs mainly appears in the southern part of Haicang, Jimei, and Xiang'an districts, and there are widespread low-low clustering areas in the northern part of Xiamen City. The high-high clustering area of REHs mainly appears in the rural areas in the north of Xiamen City, and the low-low clustering area mainly appears in the southern part of Xiamen City (as shown in Figure 7). Hot spot analysis shows that the hot spot areas of NHs appear in Xiamen Island and Haicang District, and the east-west boundary of the midlatitude area in the city shows a cold spot distribution. The hot spot area of ADCs only appears in a small part of the central area of the Tong'an District. The hot spot areas of HCA mainly appear in the western part of Haicang District, Jimei District, and the central and eastern parts of Xiang'an District, while the cold spot areas mainly exist in the rural areas in the north of Xiamen City. The main hot spot area of REH appears in the boundary areas of the middle and northern parts of Xiamen City (Figure 8).

4. Discussion

As of March 2023, under the strong promotion of the country and the reasonable planning of the Xiamen municipal government, a series of achievements have been

made in the construction of ECSFs in Xiamen. However, there are still gaps in the equity of elderly care resource utilization in achieving the goal of a 15-min living circle and the 2035 vision, and urgent efforts are needed to address this issue.

4.1. Distribution Patterns and Causes of ECSF in Xiamen City.

Overall, the existing ECSFs in Xiamen demonstrate an imbalanced spatial distribution, with a higher concentration on Xiamen Island and fewer facilities in the surrounding areas. This pattern is characterized by the dominance of facilities on Xiamen Island and multiple core clusters in the areas outside the island. Specifically, NHs are primarily located in more prosperous areas, resulting in limited access to convenient long-term care for the elderly in most rural areas in the north of the city. This also poses challenges for family visits. The number of ADCs is insufficient, mainly concentrated in the Siming District, limiting the range of beneficiaries. HCAs primarily provide home-based security, daily living assistance, and basic medical care services to the elderly in surrounding communities. They are mainly concentrated in the Siming District and Huli District on Xiamen Island, with the widest coverage among all elderly care facilities. REHs primarily cater to rural elderly individuals, offering comprehensive daytime care services such as rest and recreational activities. They are mainly located outside Xiamen Island, with major clusters in the Tong'an District and Jimei District. They are less prevalent within Xiamen Island. Considering their similar functions to HCAs but with different target populations, their distribution is relatively reasonable.

There may be multiple factors contributing to this phenomenon. First, in terms of natural factors, the main topography of the Xiamen region consists of medium-low mountains, hills, plateaus, and coastal plains, generally exhibiting a northwest high to southeast low trend. The northwestern part of the area is characterized by mountains, hills, and hilly terrains, while the central-eastern part consists of plateaus and coastal plains [34]. The southeastern part comprises shallow tidal flats and artificially built-up plains. This leads to a preference for locating ECSFs in the southeastern part, making it difficult to establish clusters in the western regions. Second, in terms of historical factors, prior to the reform and opening-up, the main developed area of Xiamen was located on Xiamen Island. After the reform and opening-up, the urban area gradually expanded from the island toward the northern inland regions [35]. However, the distribution of ECSFs is deeply influenced by the urban development zones in Xiamen. The island area was developed earlier, with relatively complete supporting facilities, while the areas outside the island have a shorter development history, and both the coverage and construction density are in need of improvement. Third, in terms of economic development factors [36], Siming District and Huli District, located on Xiamen Island, are among the first batch of economic special zones in China and have a higher level of economic development. They are more likely to have a concentration of high-level public service

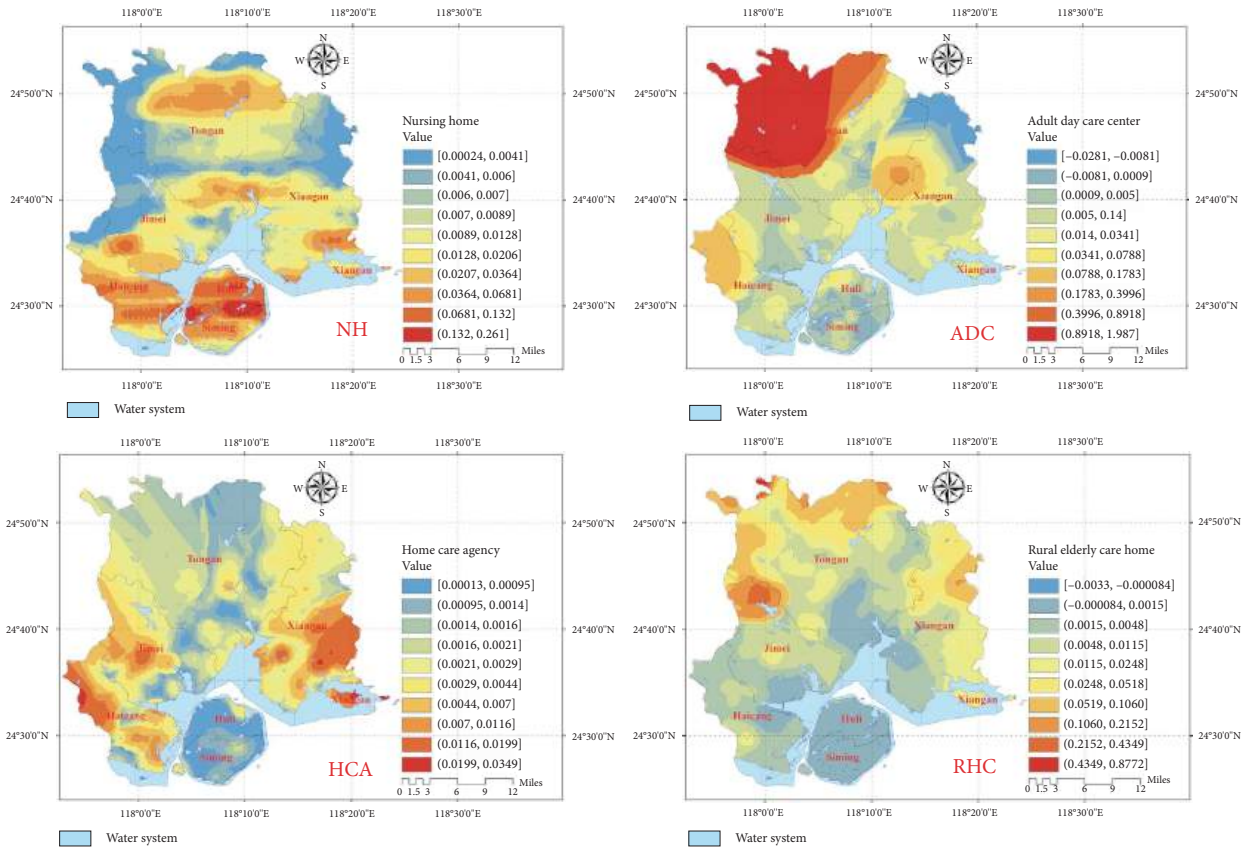

FIGURE 6: Accessibility analysis results of ECSFs.

TABLE 3: Global autocorrelation analysis results.

ECSF	Moran's I	Z-score	p value	Observed general G	Z-score	p value
NH	0.34611	45.32629	< 0.00001	0.001312	50.4855	< 0.00001
ADC	0.299089	16.7353	< 0.00001	0.009919	12.25809	< 0.00001
HCA	0.362659	27.20153	< 0.00001	0.001932	48.85721	< 0.00001
REH	0.777853	39.9211	< 0.00001	0.005048	53.02876	< 0.00001

facilities. The districts of Haicang, Jimei, Tong'an, and Xiang'an, located outside the island, have received focused planning in recent years, forming smaller scale clusters of ECSFs in their respective regional centers. However, in areas beyond these centers, the number of ECSFs is limited and their distribution is sparse. Lastly, while policy planning plays a guiding role in the rational allocation of ECSFs within the city, it can also influence the layout and equity of such facilities [36]. The supply of elderly care services comes from various sources, including the government, private capital, and social forces. These entities, driven by the pursuit of maximum benefits, make location choices for different types of ECSFs, leading to spatial disparities in the distribution of public service facilities [37]. For example, HCAs and REHs often involve government capital investment [38], resulting in more reasonable site selection that aligns well with their respective functions.

4.2. Existing Deficiencies and Potential Improvement Methods for the Accessibility of Various ECSFs. In terms of accessibility, the evaluation of NHs reveals that high-value areas are mainly located in Haicang District, Siming District, and Huli District, while large low-value areas are found in the peripheral rural areas in the northern part of Xiamen. Considering the government's recent efforts in developing the northern urban areas and the future direction of urban expansion toward the periphery, it is recommended that the government planning departments increase the construction of NHs in the peripheral areas. This would help increase the quantity and scale of facilities, contributing to a more rational allocation of public resources and greater equity in social services. If private enterprises refuse to establish NHs in rural areas, an alternative approach could be to develop corresponding NHs in suburban areas based on REHs. This would implement a "build first, optimize later" development

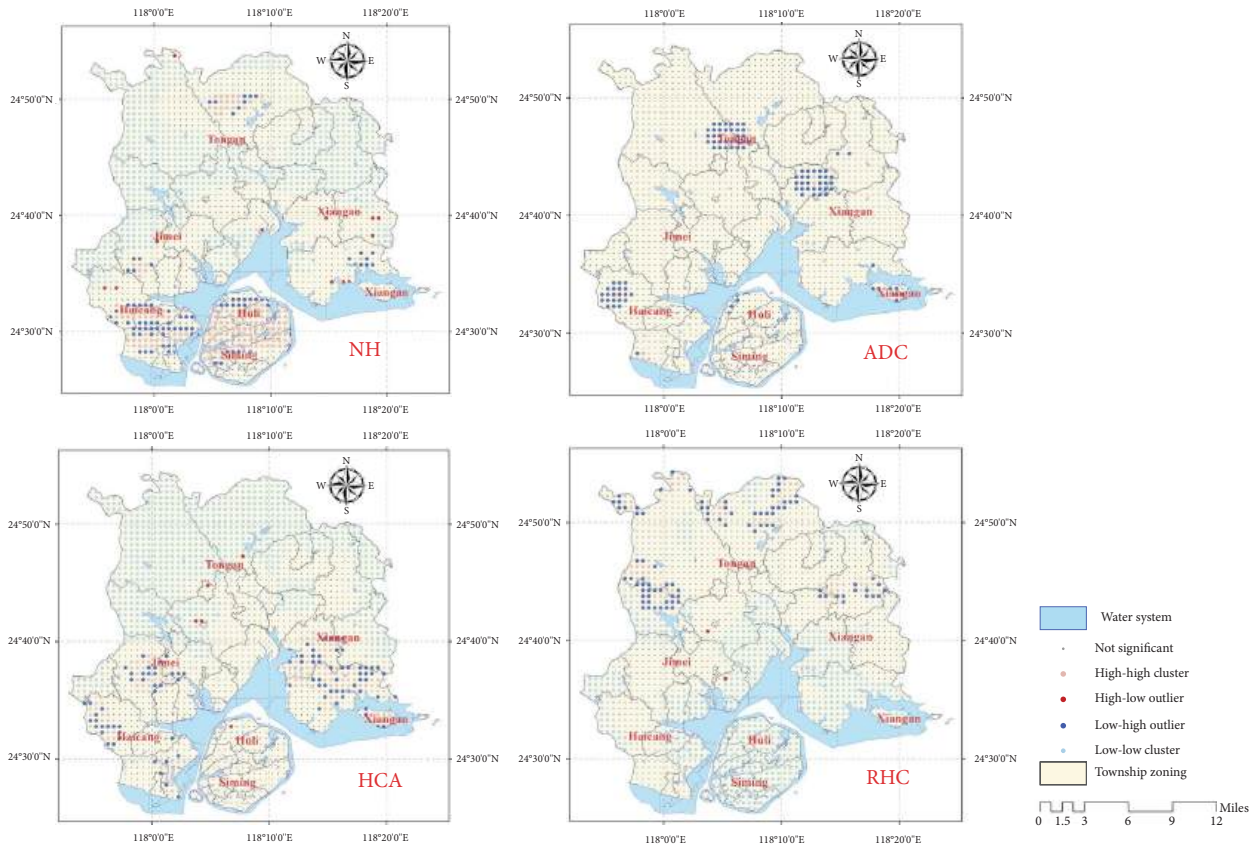

FIGURE 7: Clustering and outlier analysis results of various ECSFs.

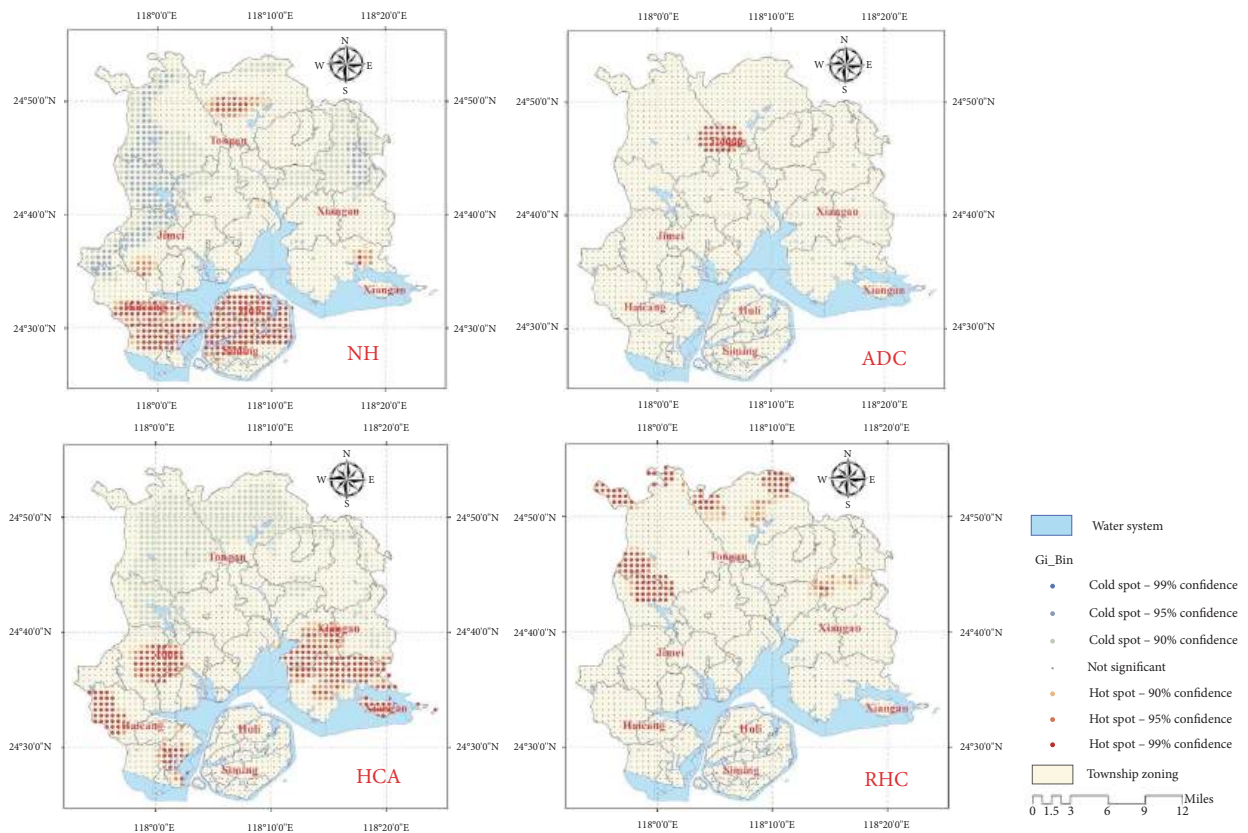

FIGURE 8: Analysis results of cold and hot spots of various ECSFs.

approach, gradually achieving full coverage of NHs in rural areas and providing convenient long-term care services for rural residents.

Previous studies have indicated that ADCs, as the most important ECSFs at the community level in the context of community-based aging, are widely recognized by many older adults. A study conducted in Sichuan Province showed that over 60% of community-dwelling older adults expressed their willingness to choose the elderly care model provided by ADCs. However, the current situation in Xiamen shows that the construction of ADCs is not well planned, and there are even areas with negative values in terms of accessibility evaluation. This suggests that the policy planning departments should focus on the construction of ADCs in the future, expanding their quantity and coverage, especially in the northeastern part of Xiamen.

It is worth noting that the main construction areas of HCAs are located in Siming District and Huli District, but the accessibility evaluation shows that this area is a low-value area. This indicates that a significant portion of urban elderly residents are unable to conveniently access elderly care services due to the concentration of population and the small service radius of HCAs. Considering the limited geographical area of Xiamen Island, we suggest that unused houses and land in densely populated areas be converted into ECSFs. This approach would not only reduce the waste of community resources but also increase the density of relevant HCAs. It would make it easier for mobility-impaired elderly individuals to access the necessary care services in their living environment. In addition, converting or building new facilities can help alleviate the financial burden on the government's elderly care funds [39].

Indeed, in comparison, REHs have shown excellent accessibility evaluation results, with high-value areas primarily located in rural areas. In the future, it would be beneficial to expand the scale of existing REHs, improve their medical equipment and staffing, and expand their service coverage area. This would help overcome the unequal distribution of elderly care resources caused by geographical barriers. By expanding the reach of REHs, more elderly individuals in rural areas can access the necessary care services, ensuring a more equitable distribution of elderly care resources.

Furthermore, the research results indicate significant spatial heterogeneity in the accessibility of various types of ECSFs, characterized by distinct hot spots and cold spots. Since accessibility evaluation is based on specific road network distances, the establishment of a "15-min living circle" standard emphasizes walking as the primary mode of transportation for the elderly. The development of transportation infrastructure will have a significant impact on the accessibility of ADCs, HCAs, and REHs for older adults [40]. Therefore, enhancing the road network infrastructure in the areas outside Xiamen Island, particularly in the northwest and northeast rural regions, through measures such as increasing the number of road branches and opening up intersecting roads [41], would contribute to improving the convenience of elderly individuals in accessing care services and enhancing their overall well-being.

5. Limitations

Despite using multiple methods to comprehensively evaluate the accessibility of ECSFs in Xiamen City in this study, there are still some limitations: The elderly population in each region in this study was predicted and may deviate from the actual situation, the service range of elderly care facilities was set based on a large number of previous studies and government documents, and the research results match the actual situation in Xiamen City and can reveal accessibility issues, but there may be more appropriate numerical settings. In the future, we plan to use more real data to evaluate the spatial distribution equity of elderly care facilities nationwide.

6. Conclusions

This study evaluated the accessibility of elderly care services in Xiamen City based on the ECSFs and road traffic POI data obtained through web crawling technology. The results of this study have important guiding significance for managers and decision-makers to formulate relevant policies and achieve fair allocation of elderly care resources. The main discoveries are as follows: Xiamen City, as an economically developed city in Southeast China, has achieved a series of achievements in the allocation of elderly care resources and the construction of service facilities under the strong advocacy of the country and the reasonable planning of the local government. However, there are still problems of poor equity.

In order to improve the fairness of elderly resource allocation, optimize the accessibility of elderly care facilities, and enhance residents' well-being, this study proposes several recommendations. First, increasing the number of elderly care facilities should be accompanied by a focus on service quality. Second, efforts should be made to strengthen the road network infrastructure in areas outside Xiamen Island, particularly in the northwest and northeast rural regions. Third, it is suggested that government capital should be involved as a provider in the planning and construction of elderly care facilities. This participation of public capital can help reduce the service costs of elderly care facilities and mitigate their concentration, thus covering a wider range of elderly individuals and improving the overall level of elderly care services in Xiamen. Lastly, expanding the scale of existing rural happiness homes, improving their medical equipment and staffing, and expanding their service coverage area would overcome the unfair distribution of elderly care resources caused by geographical barriers.

Data Availability Statement

The data for this study were obtained from publicly available government statistical yearbooks and public website POI data. The data used to support the findings of this study are available from the corresponding author upon request.

Ethics Statement

The POI data in this study are all from public platforms (Amap and Baidu Maps) and do not involve patient privacy, so ethical approval does not apply to this study.

Consent

The authors have nothing to report.

Background. Despite the emphasis on the importance of implementing evidence-based practices, nurses did not adopt this approach as a standard. For those who have attempted to implement evidence-based practice in health care settings, the behaviour is rarely simple or straightforward. Therefore, exploring the mechanism that motivates nurses' evidence-based practice behaviour is essential to promote this practice. **Aims.** The aim of this study was to investigate the effect of the organizational climate for evidence-based practice on evidence-based practice behaviour among nurses through the mediating role of evidence-based practice competence, work control, and the intention to implement evidence-based practice. **Methods.** This study consisted of a cross-sectional design and convenience sampling to recruit 641 nurses employed in 6 hospitals in China. Five self-report instruments were used to collect the data. A structural equation model was adopted to verify the research hypotheses. IBM SPSS 26.0 and AMOS 24.0 were used for statistical analysis of the data. **Results.** The organizational climate for evidence-based practice was significantly and positively related to the nurses' evidence-based practice behaviour ($p < 0.01$). Direct effects accounted for 45.93% of the total effect. Evidence-based practice competence, work control, and the intention to implement evidence-based practice partially mediated the association between the organizational climate and evidence-based practice behaviour. The indirect effect accounted for 54.07% of the total effect. **Conclusion.** The organizational climate for evidence-based practice is critical for predicting and enhancing evidence-based practice behaviour. Evidence-based practice competence, work control, and the intention to implement evidence-based practice are intervening mechanisms that explain how the organizational climate promotes evidence-based practice behaviour. **Implications for Nursing Management.** Nursing managers should be aware of the interaction of individual and organizational factors that influence evidence-based practice behaviours among nurses. Administrators should improve the organizational climate by providing nurses with cultural and team support, mentoring, training projects, resource provisions, and more autonomy and authority at work, which are beneficial to the nurses' evidence-based practice competence, work control, and intentions to adopt evidence-based practices.

1. Introduction

Evidence-based practice is conceptualized as “clinical decision-making that considers the best available evidence, the context in which the care is delivered, client preference,

and the professional judgement of the health professional” [1]. The implementation of evidence-based practices can provide high-quality health care, reduce the incidence of complications, and decrease health care costs and resource use [2, 3]. However, putting evidence into practice seems

complex, and the implementation of evidence-based practice continues to remain low in most health care systems [4, 5]. A survey revealed that organizational climate has the greatest influence on the implementation of evidence-based practices [6], which is defined as “reflect employees’ overall assessment of their work environment” [7]. Considering that the behaviour is rarely simple or straightforward, Li et al. suggested that further research should focus on how organizational features influence implementation effectiveness [8]. The facilitation of evidence-based practice in nursing needs the organization and the individual levels [9]. Therefore, the main aim of this paper is to study the effects of the organizational climate on evidence-based practice behaviour through the mediating effect of individual factors among nurses.

For individuals, the intention to adopt evidence-based practices has been recognized as a strong precursor to subsequent utilization [10]. Consistent with the arguments in the literature, the factors that influence nurses’ willingness to engage in evidence-based practices are worthy of investigation. Evidence-based practice competence was emphasized as a significant predictor of implementation [11, 12]. Nurses also experience considerable challenges in implementing evidence-based practices due to a lack of confidence in critical appraisal skills and a low level of knowledge [13–15]. It has been demonstrated that the organizational climate, such as evidence-based practice mentoring, training, and supportive culture, is associated with competence and intention of evidence-based practices [16]. The precise mechanisms and extent to which the organizational climate influences evidence-based practice behaviours through competence and intention remain unclear. More investigations that combine these factors within a single study are needed so that we can better understand their relationships.

However, the implementation of evidence-based practices continues to remain low in China, even when nurses hold strong beliefs and knowledge about evidence-based practices [17]. One possible explanation for this inconsistency may be that individuals may possess knowledge and skills but struggle to apply them flexibly in a changing environment [18]. It has been argued that control practices can also influence evidence-based practices in a dynamic work environment [19, 20]. The perception of work control results from an interaction between the individual and the work environment [21], which is defined as “a composite of decision authority (e.g., freedom to make decisions) and skill discretion (e.g., opportunity to learn new things and develop new capabilities)” [22]. According to the literature review, nurses have a low sense of work control regarding evidence-based practice, including time constraints, work stress, inadequate resources and infrastructure, and a lack of authority and autonomy to make practice changes [10, 23, 24]. All of these factors are related to the organizational climate. The interactions among the organizational climate, work control, and the intention to engage in evidence-based practice have not been clearly explored. More investigations that combine these factors within a single study are needed so that we can better understand their relationships.

Most previous studies have focused on the impact of various factors on evidence-based practice behaviour among nurses [25], and the interactions among various factors relating to this practice have not been clearly explored. This study was based on SOR (stimuli-organism-response) theory. This theory suggests that when an individual encounters a particular stimulus (S), the psychological cognition, emotional state, and ability of the individual organism (O) will change, and thus, a response (R) in the form of a behaviour will occur [26]. Therefore, the “SOR” model allows researchers to integrate various factors into systematic theory building. This study was aimed at determining how the organizational climate for evidence-based practice (S) stimulates the occurrence of evidence-based practice behaviour (R) through the mediating effect of individual factors (O), namely, evidence-based practice competence, work control, and the intention to implement evidence-based practice. For nursing practice, these results have the potential to provide nurse leaders with theory-based evidence to support strategies toward encouraging evidence-based practice behaviour among nurses and thereby improve other outcomes for nurses, patients, and health care organizations.

2. Literature Review and Hypotheses

The aim of this study was to investigate the effect of the organizational climate for evidence-based practice on evidence-based practice behaviour among nurses through the mediating role of evidence-based practice competence, work control, and the intention to implement evidence-based practice. The hypothesized model for this study is presented in Figure 1.

2.1. Organizational Climate for Evidence-Based Practice and Evidence-Based Practice Behaviour. “Organizational climate” refers to “the collective understanding that organizational members attribute to the events, policies, practices, and procedures they encounter, along with the behaviors they observe being rewarded, supported, and expected” [27]. It primarily includes seven core dimensions: organizational philosophy, environmental atmosphere, work style, teamwork, leader support, training, and resource provision [28]. Empirical studies have shown that it represents a single, overarching factor that captures employee evaluations of how the work environment impacts their personal well-being [29]. According to the previous research study, the barriers from organizational factors to the implementation of evidence-based practice include inadequate resources and infrastructures, lack of leadership support and evidence-based practice mentors, a weak culture of evidence-based practice, and less collaboration between academics and clinics [10, 20, 30]. Most of the literature focuses on a single aspect of the organizational climate for evidence-based practice. Therefore, this study integrates existing organizational factors of evidence-based practice into the concept of organizational climate for evidence-based practice, which represents an organization’s larger social context. The first

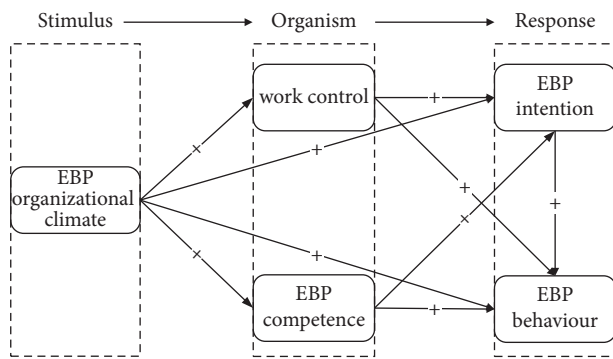

FIGURE 1: The hypothesized study model. This model presents hypothetical relationships among the variables. Note. “+” = positive correlation; EBP, evidence-based practice.

aim of this study was to examine whether an organizational climate for evidence-based practice that integrates multiple organizational factors could promote nurses’ evidence-based practice behaviour.

Hypothesis 1. The organizational climate for evidence-based practice is positively and directly related to nurses’ evidence-based practice behaviour.

2.2. Evidence-Based Practice Competence and the Intention to Implement Evidence-Based Practice as Mediators. In addition, we attempt to explore the mechanisms through which an organizational climate for evidence-based practice enhances evidence-based practice behaviour among nurses. Evidence-based practice competence and the intention to adopt evidence-based practice have been recognized as strong precursors to their subsequent utilization and actual practice [12, 25]. For individuals to implement evidence-based practice effectively, nurses need to be motivated in which they have a desire to seek out the best information that serves the needs of their patients, and they need to be competent in which they must have the necessary knowledge, skills, and attitudes that can be linked to evidence-based practice [24, 31]. However, the findings indicated that the nurses did not feel prepared for evidence-based practice. A systematic review of 18,355 nurses from 21 countries revealed that nurses did not use the best evidence in practice because of insufficient evidence-based practice knowledge and skills [30]. The lack of evidence-based practice competence results in lower confidence in implementing these practices.

Notably, the competence and intention underlying evidence-based practice have been associated with the organizational climate, such as the evidence-based practice mentoring, training, and supportive culture [16]. A survey revealed that advanced practice nurses, as “opinion leaders,” significantly influence the evidence-based practices of front-line nurses [23], and the top three sources of evidence-based practices that nurses obtained were information from specialists, instructors, and senior nurses [32]. Therefore, evidence-based practice mentoring can promote the competence of nurses in successfully engaging in evidence-based

practice. In addition, training was seen as important in explaining the likelihood of future implementation of evidence in clinical nursing practice [10]. The reason is that after continuing education programs of evidence-based practice in hospitals, nurses’ evidence-based practice knowledge scores improved [33]. The findings of Melnyk demonstrated evidence-based practice culture as a key variable that directly affects evidence-based practice knowledge, beliefs, and competency [5]. Therefore, this study was aimed at examining whether an organizational climate for evidence-based practice could promote this behaviour among nurses through evidence-based practice competence and intention.

Hypothesis 2. Evidence-based practice competence mediates the relationship between the organizational climate and evidence-based practice behaviour.

Hypothesis 3. The intention to implement evidence-based practice mediates the relationship between the organizational climate and evidence-based practice behaviour.

Hypothesis 4. Evidence-based practice competence and the intention to implement evidence-based practice play a chain mediating role between the organizational climate and evidence-based practice behaviour.

2.3. Work Control and the Intention to Implement Evidence-Based Practice as Mediators. Work control is an essential work characteristic that is generally defined as “one’s control over one’s task, conduct, and performance or the ability to have influence over one’s work and work environment to obtain a rewarding work situation, such as control of work efficiency (e.g., the method, amount, and speed for increasing efficiency), control of work resources (e.g., the perception of authority in regard to job-related information, procedures, or materials for meeting the demands of the job), and control of work environment (e.g., decoration of the work area and protection of the working environment from interference)” [34]. A sense of high work control has been demonstrated to increase work engagement and stimulate intrinsic motivation [35]. Under conditions of high work control, nurses’ performance in relation to evidence-based practice is actually fostered.

According to the literature review, the barriers to implement evidence-based practice are insufficient time for involvement in this practice, inadequate resources and infrastructure, and a lack of authority and autonomy to make practice changes [10, 24]. This result suggests that nurses have a low sense of work control when implementing evidence-based practice. When nurses perceive a lack of control over their work, particularly in relation to resources and the environment, they are less inclined to engage in evidence-based practice, even if they have sufficient evidence-based practice competence. This low engagement occurs because these factors are often beyond the control of the individual [24]. The provision of significant support to nurses, including time, funding, administrative support, and

mentors [19], enables nurses to exert greater control over their resources, environment, and efficiency. This control may facilitate nurses' willingness to implement evidence-based practices. Although existing studies lack enough investigation and further study about nurses' work control in evidence-based practice, there may be a relationship among work control, intention to implement evidence-based practice, and organizational climate for evidence-based practice. However, the exact underlying mechanism remains unclear. Therefore, this study examined whether an organizational climate for evidence-based practice could promote nurses' evidence-based practice behaviour through work control and intention.

Hypothesis 5. Work control mediates the relationship between the organizational climate and evidence-based practice behaviour.

Hypothesis 6. Work control and the intention to implement evidence-based practice play a chain mediating role between the organizational climate and evidence-based practice behaviour.

3. Methods

3.1. Design. This study was a descriptive, cross-sectional survey that gathered data from nurses in China in 2022.

3.2. Participants. The survey was conducted with a population of nurses from 6 hospitals in 6 cities in China: Beijing, Shanghai, Guangzhou, Zhengzhou, Shenyang, and Urumqi. With the help of the nursing managers, surveys were sent to the nurses using a convenient sampling method. The inclusion criteria were as follows: those who (a) had obtained the professional qualification nursing certificate from the People's Republic of China, (b) were working in the hospital during the investigation period, and (c) had at least 1 year of evidence-based practice experience. The exclusion criteria counted those who were not willing to participate or were absent during the survey.

3.3. Data Collection. Although the minimum sample size for structural equation model analysis is 200 [36], 380 to 760 participants would be considered to be the optimal sample size because of the 76 items included, according to the principle that the sample size is approximately 5 to 10 times the number of scale items [37]. Assuming a 20% attrition rate based on previous studies conducted in China [38], the minimum sample size was 456.

We explained the purpose and method of this study to the nursing managers of each hospital, invited them to serve as research assistants, and provided them with training on the study. After learning about the implementation of evidence-based practices in the hospital and obtaining permission, the researchers or trained research assistants distributed the questionnaires to the clinical departments that met the inclusion criteria. All the data were collected using electronic questionnaires. The purpose of this study

was explained, and detailed instructions were given to the guide nurses about filling out the questionnaires. After the anonymity and confidentiality of participation were explained, the nurses were informed that they were free to refuse to participate or withdraw from participation at any time without penalty. A total of 700 questionnaires were distributed, 650 of which were completed and returned to the researchers. After being checked by 2 researchers, 9 electronic questionnaires were excluded because they had the same answers (e.g., all 4s or all 5s), and 641 questionnaires (91.57%) were determined to be valid.

3.4. Instruments. Five self-report instruments were employed in this study. Two of these are widely used in China (Work Control Scale and Evidence-Based Behaviour Scale). Two were self-developed (Intention to Implement Evidence-Based Practice Scale and Organizational Climate for Evidence-Based Practice Scale), and one was a Chinese translation of the English version (Evidence-Based Practice Competency for Practicing Registered Nurses Scale). The self-developed or translated scales were tested in two stages, with stage 1 comprising the creation (or translation) and adaptation of the scales and stage 2 evaluating the psychometric properties of the scales. These 3 instruments were initially pretested among eligible participants who were excluded from this study.

3.4.1. Work Control. The 19-item Chinese version of the Work Control Scale for nurses [34] comprises three domains: control of work efficiency, control of work resources, and control of work environment. A 5-point Likert scale is used, ranging from 1 (almost not) to 5 (very much), with higher scores indicating greater levels of work control. The internal consistency reliability (0.90) and test-retest reliability (0.77) of the scale indicated good reliability [34]. Cronbach's α was 0.930 in this study.

3.4.2. Evidence-Based Practice Behaviour. Evidence-based practice behaviour was measured using the Chinese version of the Evidence-Based Practice Questionnaire (EBPQ) [39]. It comprises 3 subscales: use of evidence-based practice, attitude towards evidence-based practice, and knowledge/skills associated with evidence-based practice. The subscale "use of evidence-based practice" was adopted to measure the implementation of evidence-based practice by Anaman-Torgbor et al. [40] and consists of 6 items. All items are scored on a 7-point Likert scale ranging from 1 (never) to 7 (always), with a higher score indicating a more positive implementation of evidence-based practice. Cronbach's α of the subscale was 0.84 [39]. Cronbach's α was 0.911 in this study.

3.4.3. Evidence-Based Practice Competence. The Evidence-Based Practice Competency for Practicing Registered Nurses Scale [16] was modified by our team using the "translation-back-translation-cultural adaptation" procedure in accordance with Chinese cultural background.

This scale consists of 13 items, which are rated on a 4-point Likert scale ranging from 1 (not competent) to 4 (highly competent). A higher score indicates a higher level of self-rated competence. The internal consistency was 0.98 [5]. Cronbach's α was 0.917 in this study.

3.4.4. Intention to Implement Evidence-Based Practices. The nurses' intentions to implement evidence-based practices were measured by using a scale developed by our team in this study. This scale consists of 4 items, which are rated on a 5-point Likert scale ranging from 1 (strongly disagree) to 5 (strongly agree), with higher scores indicating greater levels of intention to implement evidence-based practice. Cronbach's α was 0.865 in this study.

3.4.5. Organizational Climate for Evidence-Based Practice. The organizational climate for evidence-based practice was measured by using a scale developed by our team in this study. It consists of 28 items divided into 7 dimensions, including the organizational philosophy, environmental atmosphere, work style, teamwork, leader support, training, and resource provision. All the items are scored on a 5-point Likert scale ranging from 1 (strongly disagree) to 5 (strongly agree). Higher scores indicated a stronger organizational climate for evidence-based practice. The scale has good internal consistency for the overall scale (Cronbach's $\alpha = 0.948$) and 7 dimensions (Cronbach's $\alpha = 0.851, 0.810, 0.831, 0.887, 0.869, 0.883, \text{ and } 0.872$) in this study.

3.5. Data Analysis. IBM SPSS 26.0 and AMOS 24.0 were used for the statistical analysis of the data. Descriptive statistics were used to quantify the collected data. The mean and standard deviation were used to describe continuous variables, and the frequency and percentage were used to describe categorical variables. The correlations among evidence-based practice competence, work control, the intention to implement evidence-based practice, the organizational climate, and evidence-based practice behaviour were analysed using Pearson correlations. Structural equation modelling was used to test the hypothesized study model. The following criteria were used to evaluate the model: $\chi^2/df < 5$, RMSEA < 0.08 , GFI > 0.9 , NFI > 0.9 , IFI > 0.9 , TLI > 0.9 , and CFI > 0.9 [41]. The bootstrap method was used to iterate 5000 times to estimate the mediating effect. The confidence intervals were 95% confidence intervals and did not contain 0, which signifies statistical significance.

3.6. Ethical Approval. Ethical approval was not needed because no unethical behaviour was present in this study, and our study did not involve human clinical trials or animal experiments. The professionals were invited to participate voluntarily through the electronic questionnaire. They were informed about the objectives of the study, with clarification that their participation was completely anonymous and that submitting the questionnaire granted their consent for participating in the study.

4. Results

4.1. Demographic Profile of Participants. Table 1 shows that most of the nurses who completed the survey ($n = 641$) were female (97.04%), had worked in the Department of Internal Medicine (64.27%), had a bachelor's degree (79.72%), had teaching experience (52.57%), had research experience (24.80%), and had 6–15 years of clinical experience (58.97%).

4.2. Descriptive Statistics and Correlational Analysis of Variables. As presented in Table 2, the mean overall score of the organizational climate for evidence-based practice was 3.66 (SD = 0.57), the evidence-based practice competency score was 2.65 (SD = 0.55), the work control score was 3.48 (SD = 0.60), the intention to implement evidence-based practice score was 3.90 (SD = 0.81), and the evidence-based practice behaviour score was 4.16 (SD = 1.32). The correlation analysis results show that there were positive impacts among the independent variable (organizational climate for evidence-based practice), the dependent variable (evidence-based practice behaviour), and the mediating variables (competence, work control, and intention for evidence-based practice implementation). Tables S1–S5 show the results of the *t*-test or analysis of variance (ANOVA) for the variables above.

4.3. Verification of Research Hypotheses. First, we assessed the measurement model, which included five latent constructs (organizational climate for evidence-based practice, evidence-based practice competence, work control, intention to implement evidence-based practice, and evidence-based practice behaviour) and 23 observational variables. Confirmatory factor analysis revealed that the model fit the data well ($\chi^2 = 288.973$, $df = 221$, $\chi^2/df = 1.308$, RMSEA = 0.022, GFI = 0.963, NFI = 0.962, IFI = 0.991, TLI = 0.990, and CFI = 0.991) (see Figure 2), and all the indicators were significantly loaded on the corresponding constructs.

Second, as presented in Figure 2, we verified whether the organizational climate for evidence-based practice positively affects evidence-based practice behaviour (Hypothesis 1). Table 3 shows that the organizational climate for evidence-based practice significantly affected evidence-based practice behaviour ($\beta = 0.25$, $p < 0.001$). Table 4 reveals the direct, indirect, and total effects of the final model. The results demonstrated that the 95% confidence intervals of all of the effects did not overlap with zero, which indicated that all the direct and indirect effects were significant. Direct effects accounted for 45.93% of the total effect. This result indicates that the organizational climate for evidence-based practice can predict evidence-based practice behaviour well.

Lastly, we tested a mediating effect model to verify whether evidence-based practice competence, work control, and intention to implement evidence-based practice mediate the relationship between organizational climate and evidence-based practice behaviour. Table 3 shows that organizational climate for evidence-based practice significantly affected evidence-based practice competence

TABLE 1: Demographic profile of the participants ($n = 641$).

($\beta = 0.45$, $p < 0.001$), which in turn had a positive effect on evidence-based practice behaviour ($\beta = 0.28$, $p < 0.001$). The indirect effect of the organizational climate on evidence-based practice behaviour via evidence-based practice competence accounted for 22.24% of the total effect (Hypothesis 2). The organizational climate for evidence-based practice significantly affected the intention to implement evidence-based practice ($\beta = 0.23$, $p < 0.001$), which had a positive effect on evidence-based practice behaviour ($\beta = 0.14$, $p = 0.003$). The indirect effect of the organizational climate on evidence-based practice behaviour via intention accounted for 5.79% of the total effect (Hypothesis 3). The organizational climate for evidence-based practice significantly affected the work control ($\beta = 0.62$, $p < 0.001$), which had a positive effect on evidence-based practice behaviour ($\beta = 0.17$, $p = 0.002$). The indirect effect of the organizational climate on evidence-based practice behaviour via work control accounted for 18.99% of the total effect (Hypothesis 5). The data indicated that evidence-based practice competence, work control, and intention played a partial

mediating role between the organizational climate and evidence-based practice behaviour, and the indirect effect accounted for 47.02% of the total effect. Moreover, evidence-based practice competence significantly affected the intention to implement evidence-based practice ($\beta = 0.30$, $p < 0.001$), and work control significantly affected the intention to implement evidence-based practice ($\beta = 0.24$, $p < 0.001$). The data demonstrated that competence and intention, as well as work control and intention, played a chain mediating role in the influence of the organizational climate on evidence-based practice behaviour (Hypotheses 4 and 6). The chain indirect effects accounted for 3.25% and 3.80% of the total effects, respectively.

5. Discussion

According to the analysis of the survey data, the organizational climate for evidence-based practice positively affected evidence-based practice behaviour. This finding was supported by a study that revealed that nurses working in

Goodness-of-fit-indices
 $\chi^2=288.973$, $df=221$, $\chi^2/df=1.308$, $RMSEA=.022$,
 $GFI=.963$, $NFI=.962$, $IFI=.991$, $TLI=.990$, $CFI=.991$

Note. EBP, evidence-based practice.

departments with better organizational contextual features (organizational culture; leadership; networks and communication; resources; evaluation, monitoring, and feedback; and champions) engaged in greater use of evidence-based practice [8]. Leadership engagement, the availability of resources, and the provision of educational support, which are the three major components of organizational climate, are all key indicators of whether practice climates are conducive to evidence-based practice implementation [27]. This is because nurses will implement evidence-based practices more proactively to a greater extent when they perceive their

organizational climate as more supportive. In addition, positive feedback from nursing managers can enhance nurses' sense of responsibility and accomplishment and foster the use of evidence-based practices in a virtuous circle. Thus, improving the organizational climate for evidence-based practice in the department makes great sense in promoting evidence-based practice behaviour.

In this survey, evidence-based practice competence mediated the relationship between the organizational climate and evidence-based practice behaviour, which contributed the most to the indirect effect. We can predict that

TABLE 4: Confidence interval of mediating effect value.

Path	Effect	S.E.	95% LCI	95% UCI	Ratio (%)
Direct effect					
EBP organizational climate → EBP behaviour	0.254	0.075	0.107	0.402	45.93

Note. EBP, evidence-based practice.

professional nurses present weakness in the implementation of evidence-based practice related to the lack of evidence-based practice competence. This finding is consistent with the results of previous research [42, 43]. Research has demonstrated that nursing education and training have a positive influence on the successful achievement of evidence-based practice competence [44]. However, prior studies have typically focused on “theory-based” education, which does not meet the needs of complex, dynamic clinical environments [31]. Researchers refer to this issue as the “theory-practice gap.” Nurses face changes in the context of health care services, such as the emergence of constantly updated evidence, medical knowledge and technology, different stakeholder attitudes, and dynamic clinical resources and conditions. Therefore, we should attempt to improve evidence-based practice competence continuously, not only during the undergraduate years but also throughout the careers of health professionals. As one of the core factors during a professional career, a good organizational climate can promote evidence-based practice competence in the following ways: (a) ensuring nurses’ knowledge and skills in complex clinical environments (e.g., through “practice-based” training, mentoring, teamwork, and work styles) and (b) enhancing attitudes and beliefs about evidence-based practices (e.g., through leader support, culture, and resource provision).

Furthermore, work control mediated the relationship between organizational climate and evidence-based practice behaviour, which contributed to the second indirect effect. Although evidence-based practice competence is considered the core factor of implementing evidence-based practice, some studies have found that even nurses who possess evidence-based practice competence are not necessarily able to use it flexibly in a changeable environment [18]. This lack of application is a potential result of neglecting nurses’ perceptions of their environment, resource reconfiguration, and control of themselves. This study revealed that work control, which is the ability to cope with the actual working situation, may be another important individual factor affecting evidence-based practice behaviour. According to our survey, nurses generally believe that controlling resources (e.g., financial resources, policy, staffing, and infrastructure) and the environment (e.g., atmosphere and work style) are

the most difficult factors, and these issues can be solved by improving the organizational climate for evidence-based practice. In addition, nursing managers need to provide nurses with more opportunities and incentives to promote evidence-based practices, such as further study, bonuses, and staff development. Managers can improve nurses’ control of their work by (a) creating more opportunities for nurses to work more freely and autonomously; (b) attracting nurses to participate in management decisions, such as the formulation of department rules and regulations, performance evaluations, and salary incentive systems; and (c) assigning young and highly educated nurses with the ability to challenge and innovate work tasks to enhance their sense of accomplishment.

Lastly, the study demonstrated that the intention to implement evidence-based practice mediates the relationship between organizational climate and evidence-based practice behaviour. Moreover, evidence-based practice competence and the intention to implement evidence-based practices had a chain mediating effect on the relationship between organizational climate and evidence-based practice behaviour, and work control and intention had the same chain mediating effect. Intention is the tendency and motivation before taking action, which is seen as a strong precursor to the subsequent utilization of evidence-based practice [45]. A more recent study also identified several factors that strengthened intentions to adopt evidence-based practices, including nurses’ capabilities, beliefs, attitudes, support received from nurses and other faculty members, adequate clinical and academic support, and Internet and journal access [46, 47]. Nurses are more confident and willing to use evidence-based practices, which is significantly associated with both nurse variables (evidence-based practice competence and control of work) and organizational variables (organizational climate for evidence-based practice).

6. Limitations

There are several limitations in our study that need to be improved upon through follow-up research. First, our study was conducted in the form of a self-report questionnaire, and the results are relatively subjective. Second, our research

was only performed in some provinces in China. Therefore, the sample has some limitations. In future research, we will further expand the sample size and involved regions to make the sample more representative.

7. Conclusions

This study confirmed that the organizational climate for evidence-based practice is critical for predicting and enhancing evidence-based practice behaviour. Evidence-based practice competence, work control, and the intention to implement evidence-based practice are intervening mechanisms that explain how organizational climate promotes evidence-based practice behaviour.

8. Implication for Nursing Management

Our findings highlight the need for nurse managers to be aware that the organizational factor (the organizational climate for evidence-based practice) influences evidence-based practice behaviour through individual factors (evidence-based practice competence, work control, and intention to implement evidence-based practice). This relationship suggests that nursing managers should pay attention not only to the factors influencing evidence-based practice behaviour but also the mechanism for the interaction between these factors. Although evidence-based practice competence is the most important individual factor for evidence-based practice behaviour according to previous studies, work control should be enhanced as another important individual factor. Managers should improve the organizational climate by providing nurses with culture and team support, training projects, and resource provisions. They should also enforce more autonomy and authority at work, which are beneficial to evidence-based practice competence, work control, and the intention to adopt evidence-based practice.

Data Availability

The data that support the findings of this study are available upon request from the corresponding author. The data are not publicly available due to privacy or ethical restrictions.

Ethical Approval

Ethical approval was not needed because no unethical behaviour existed in the study, and our study did not involve human clinical trials or animal experiments.

Conflicts of Interest

The authors declare that there are no conflicts of interest regarding the publication of this paper.

Acknowledgments

We would like to express our gratitude to the nurse participants from the six hospitals and all the nurses involved with the study for their support and cooperation.

Supplementary Materials

Tables S1–S5 show the results of the *t*-test or analysis of variance (ANOVA) for the following variables: organizational climate, evidence-based practice competence, work control, and intention to implement evidence-based practice and evidence-based practice behaviour. (*Supplementary Materials*)

Nurses' turnover intention has increased since the COVID-19 pandemic. Emotional labor is reportedly high among nurses in Korea, and a positive psychological capital can help reduce turnover intention. This cross-sectional study investigated the factors influencing turnover intention in nurses during the COVID-19 pandemic. Survey data were collected from 155 nurses caring for patients with COVID-19 at a university hospital in South Korea in March 2022. Self-reported and paper-based questionnaires on emotional labor, positive psychological capital, and turnover intention were employed. The mean values for emotional labor, positive psychological capital, and turnover intention were 54.52/80, 58.03/90, and 38.92/50, respectively, and 77.8% of nurses reported planning to quit working. Turnover intention correlated with emotional labor ($r = 0.17$; $p = 0.041$) and had no significant relationship with positive psychological capital. Sex ($\beta = 0.24$; $p = 0.003$) and emotional labor ($\beta = 0.18$; $p = 0.019$) affected turnover intention, with 9% explanatory power. Female nurses caring for patients with COVID-19 had a higher turnover intention than male nurses. Finally, the higher the emotional labor of nurses caring for patients with COVID-19, the higher the turnover intention. To reduce the turnover intention of nurses, hospitals need to help them enhance their emotional labor and positive psychological capital by establishing measures such as emotional coaching programs or psychological capital interventions.

1. Introduction

Coronavirus disease (COVID-19) is an infectious respiratory disease caused by the SARS-CoV-2 virus [1]. The current COVID-19 pandemic has placed greater burdens on the already exhausted nursing workforce, acting as a strong determinant of nurse resignation [2]. Accordingly, nurses' turnover intention has drastically increased since the pandemic outbreak [3], with a higher level in those caring for patients with COVID-19 than in those in general wards [4]. The International Council of Nurses (ICN) also noted the worsening high turnover rate of nurses and the shortage of nursing staff due to the COVID-19 pandemic, saying governments are working on mitigating the risk of increased turnover among nurses and improving nurse retention [5].

Along with these efforts, it is necessary to make efforts to lower nurses' turnover intention by identifying the factors affecting such intention among nurses caring for patients with COVID-19.

Nurses in the front line against the COVID-19 pandemic faced substantial changes in their workplace and experienced profoundly emotional labor in the care process of patients with COVID-19 [6]. Emotional labor refers to efforts to control one's actual emotions for effective job performance and to express specific emotions required by organizational norms [7]. Given that nurses constantly communicate with patients, they have to manage their own actual feelings [8]. The levels of nurses' emotional labor were above the average during this pandemic [8]. Higher levels of emotional labor were associated with higher levels

of nurses' turnover intention, and emotional labor was the strongest impact factor on turnover intention [9]. Therefore, in order to identify the factors to lower the turnover intention of nurses in charge of COVID-19 patients, it is necessary to investigate the effect of emotional labor of nurses in charge of patients with COVID-19 on turnover intention.

Nurses in the front line of the fight against COVID-19 are at risk of contagion and death, as well as encounter with a complex and unexpected scenario, which experiences the exposure of the nurses to difficulties that may hinder their emotional wellbeing [6]. A positive psychological capital implies a positive mental state that allows a person to achieve goals and improve performance according to individual psychological strengths [10]. Positive psychological capital has four dimensions: self-efficacy, optimism, resilience, and hope [11]. It also contributes to improving organizational performance, job satisfaction, and life satisfaction [12] and is a primary variable that reduces anxiety and depression experienced by healthcare professionals during the pandemic [13]. In 4865 Chinese nurses, psychological capital was a negative predictor of turnover intention; the higher the psychological energy, the more stable and the lower their intention to leave [14]. In other words, increasing the positive psychological capital contributes to greater job retention. Based on this background, there is a possibility that positive psychological capital may affect the turnover intention of nurses in charge of COVID-19 patients in Korea. Therefore, investigating the impact factor of positive psychological capital of nurses caring for patients with COVID-19 on turnover intention in Korea may be important.

During the COVID-19 pandemic, several studies have been conducted on nurses' turnover intention [2–4, 15], emotional labor [6, 8, 9], and positive psychological capital [14, 16, 17] separately. The studies described various emotional states and emotional labor experienced by nurses during the COVID-19 pandemic [6, 8] and the relationship between emotional labor and turnover intention [9, 18]. In addition, studies were conducted on the mediating role of psychological capital between nurses' COVID-19 fear and public health education [16], the relationship between psychological capital and turnover intention [14], and psychological capital's mediating role between perceived stress and posttraumatic stress disorder (PTSD) symptoms [17]. Moreover, it was also found that the turnover intention of nurses increased due to the increase in the workload (ICN, n.d.), fatigue [4], and stress [15] of nurses. However, few research studies have been conducted on the impact of emotional labor and positive psychological capital on turnover intention for nurses caring for COVID-19 patients. Nurses' turnover intention has been an important issue since the COVID-19 pandemic not only in South Korea but also internationally [2–4, 14, 15, 18–20], and their indicators should be identified to reduce it. Emotional labor and positive psychological capital are factors that affect nurses' turnover intention as mentioned earlier. Thus, this study aimed to investigate the impact of emotional labor and psychological

capital on the turnover intention of nurses caring for patients with COVID-19 in South Korea at a time when the pandemic is not over.

2. Methods

2.1. Study Design and Participants. The cross-sectional study design was used. Using convenience sampling, nurses working in three shifts and caring for patients with COVID-19 at a general hospital with more than 500 beds in South Korea were recruited. Sample size was calculated using the G*Power 3.1 program [21], with a significance level of 0.05, a medium effect size of 0.15, a power of 0.90, and 10 predictive factors. The required sample size for linear multiple regression was 147, but 170 paper-based questionnaires were distributed. A total of 158 nurses answered, with a survey response rate of 86.5%. However, one was incomplete, and two were duplicate. Ultimately, 155 responses were analyzed.

2.2. Instruments. Sociodemographic and working characteristics, such as age, sex, marital status, education, working department, clinical experience, length of experience caring for patients with COVID-19, and experience caring for patients with Middle East respiratory syndrome (MERS) or severe acute respiratory syndrome (SARS), were included in the structured questionnaires.

Emotional labor was assessed using the Emotional Labor Scale for nurses developed by Hong [22]. This 16-item scale consists of three subscales: emotional modulation efforts in the profession (7 items), patient-focused emotional suppression (5 items), and emotional pretense by norms (4 items). The items are scored on a 5-point Likert scale ranging from 1 ("not at all") to 5 ("very much"), and the total score is within 16–80. High scores indicate greater emotional labor. Cronbach's α during the scale development was 0.81 [22], whereas that in this study was 0.87.

Furthermore, positive psychological capital was evaluated using the Korean version of the Psychological Capital Questionnaire 24 (PCQ-24) developed by Luthans et al. [11] and revised by Lim [23] to suit the domestic situation in Korea. This 18-item scale has four subscales: self-efficacy (5 items), optimism (5 items), hope (5 items), and resilience (3 items). The items are scored on a 5-point Likert scale ranging from 1 ("not at all") to 5 ("very much"); the total score ranges 18–90, with higher scores indicating higher positive psychological capital. Cronbach's α during the revised scale was 0.92 [23], whereas that in this study was 0.91.

For measuring nurses' turnover intention, the Korean Nurse Turnover Intention Scale (K-NTIS) developed by Yeun and Kim [24] was used. This 10-item scale consists of three subscales: job satisfaction (4 items), interpersonal relationships (3 items), and work performance (3 items). Each item is scored on a 5-point Likert scale ranging from 1 ("not at all") to 5 ("very much"); the total score ranges 10–50, with higher scores indicating higher turnover intention. Cronbach's α during the scale development was 0.83 [24], whereas that in this study was 0.87.

2.3. Data Collection and Ethical Considerations. This study was conducted from March 18 to 27 of 2022 after being approved by the Clinical Trial Review Committee of Kyungpook University Hospital (IRB No.: KNUH 2022-02-014-002). Permission to collect data was obtained upon visiting the nursing departments that managed the quarantine area for patients with COVID-19 (2 intensive care units, 2 wards, and 1 emergency room). Given that the participants worked in three shifts, we visited the corresponding nursing department several times before and after shifts to explain the study's purpose and methods. The researcher explained enough so that each participant could complete the survey only once, and the permission form was prepared individually according to the IRB guidelines. The questionnaire was returned after that to provide sufficient time for the subjects.

Before data collection, written informed consent was obtained from nurses who wanted to participate in this study. The consent form acknowledged that the participants joined the research voluntarily and that they were explained that they could withdraw at any time without disadvantages. Furthermore, all data would be used for academic research purposes, and personal information would remain confidential. The participants received a small gift for completing the survey.

2.4. Data Analyses. The data were analyzed using SPSS Statistics 28.0. The participants' emotional labor, positive psychological capital, and turnover intention were measured using descriptive statistics to calculate the means and standard deviations. The differences of turnover intention according to the participants' characteristics were analyzed using a *t*-test and ANOVA. The correlation between variables was evaluated using Pearson's correlation coefficient, and the effects of the participants' emotional labor and positive psychological capital on turnover intention were determined by multiple regression analysis.

3. Results

3.1. Sociodemographic and Working Characteristics. Table 1 shows the participants' characteristics. Of the 155 participants, 92.9% were females and 72.3% were 22–29 years old, with a mean age of 29.15 years. Regarding marital status, 81.3% were single. In addition, 88.4% held a bachelor's degree or higher. The current place of work was mostly intensive care unit (ICU) (47.7%), followed by wards (33.5%) and emergency room (ER) (18.7%). The mean length of clinical experience was 5.92 years, with 60% participants having less than 5 years. The mean length of experience in caring for patients with COVID-19 was 10.81 months, with 51% under 6 months. Moreover, majority of the participants (94.8%) had no experience caring for patients with an emerging infectious disease such as MERS or SARS.

3.2. Descriptive Statistics and Differences on Turnover Intention. The mean scores of emotional labor, positive psychological capital, and turnover intention were

54.52 ± 7.55, 58.03 ± 9.06, and 38.92 ± 6.07, respectively. Table 1 shows the differences in turnover intention according to the participants' characteristics. A significant difference by sex was observed; female nurses had a higher turnover intention score than male nurses ($t = -3.31$; $p < 0.001$). However, no significant differences in turnover intention were noted according to age, marital status, education, department, clinical experience, length of experience caring for patients with COVID-19, and experience of caring for patients with MERS or SARS.

3.3. Relationships between Variables. Table 2 shows the results of the correlation analyses of emotional labor, positive psychological capital, and turnover intention. Emotional labor had statistically significant positive correlations with turnover intention ($r = 0.17$; $p = 0.041$) and positive psychological capital ($r = 0.17$; $p = 0.041$). However, no significant correlation was noted between positive psychological capital and turnover intention.

3.4. Multivariable Linear Regression Analysis. Table 3 demonstrates the regression analysis results of the effects of emotional labor and positive psychological capital on turnover intention. Before the regression analysis, the multicollinearity between independent variables was examined. The tolerance ranged between 0.94 and 0.97, and all values were above 0.1. In addition, the variance inflation factor was 1.03–1.07. Thus, no problem in multicollinearity was observed between the independent variables. Moreover, the Durbin–Watson value for the independence test of the residuals was 1.86, which is close to the reference value of 2, implying that autocorrelation problem of the error did not occur.

In controlling the sex variable, which showed a significant difference in turnover intention, a dummy variable was changed. At step 1, sex was a significant impact factor on turnover intention ($\beta = 0.26$; $p = 0.001$). At step 2, sex ($\beta = 0.24$; $p = 0.003$) and emotional labor ($\beta = 0.18$; $p = 0.019$) were affecting turnover intention. In this context, female nurses and having greater emotional labor were associated with a higher turnover intention, and the explanatory power of these variables for turnover intention was 9% (Table 3).

4. Discussion

In this study, the mean score of emotional labor among the nurses caring for patients with COVID-19 was 54.52, which is consistent with the previous study that the mean was 55.62 for 171 nurses working at comprehensive nursing care service wards in South Korea [25]. Before or during the COVID-19 pandemic, nurses' emotional labor was above average. During the pandemic, it became severe because of barriers caused by personal protective equipment (PPE) use, low trust relationships, and negative responses from infected patients [6]. For the positive psychological capital of our participants, the score was 58.03. This result was similar to Mubarak et al. [16] study, which the positive psychological

capital score was 56.52 for 243 Pakistan nurses during the COVID-19 pandemic. The positive psychological capital is important for managing psychological pain [26] and reducing nurses' fear of COVID-19 [16]; thus, developing measures to increase it is necessary. Regarding the turnover intention of nurses caring for patients with COVID-19, the score was 38.92, which is consistent with the previous study that the score was 31.50 for 174 Korean nurses in 2022 [19]. The higher turnover intention present study may have resulted from the sudden and steep increase in nurses' work, which included wearing PPE while caring for patients with COVID-19, and the large number of patients being hospitalized [4].

Our study results indicated that emotional labor had a significantly positive correlation with positive psychological capital. Nurses with maladaptive cognitive emotional regulation experienced emotional problems, often associated with mental disorders such as depression or anxiety [17]. Nonetheless, possibly, through nurses' emotional labor experience, they were able to quickly recognize their patients' needs and adjust their emotions according to organizational norms, thereby positively influencing their role and job satisfaction improvement and enabling them to efficiently manage situational emotions [27]. The higher the level of psychological capital, the lower their intention in our current study. This is consistent with a previous study

involving 4865 nurses from 21 general hospitals randomized in China [14]. Many nurses have complained of mental health-related problems resulting from the prolonged COVID-19 situation [28, 29]; these problems appear to be a factor leading them to leave work. Nurses with a higher level of psychological capital can resolve difficulties and seek external help, and they are more stable at work; thus, their turnover intention is reduced [14].

In this study, sex was the leading factor influencing turnover intention, followed by emotional labor, with 9% explanatory power. At first, female nurses had a higher turnover intention than male nurses. Most previous studies [15, 20, 30] were shown contrary to our result. Mirzaei et al.'s [15] findings reported that male nurses had a higher turnover intention at a hospital in Iran during the COVID-19 outbreak, which might be a different culture of Iran that men having more difficulty tolerating a work setting where it is out of control during an outbreak of an infectious disease. Male nurses reported a greater inclination than female nurses in turnover intention of 1,245 Norwegian nurses [20]. It is a possible explanation on the current result that most nurses are composed of women in the current study and our country, and men should be the head of the family and have financial responsibilities in the Confucian culture. Therefore, sex differences in turnover intention should be further investigated, with equal sex ratios. In addition, intention turnover is different by sex in previous studies [31, 32], and possible explanations were follows: Alsaraireh et al. [31] found that job satisfaction had a negative correlation with turnover intention and that men nurses had a lower job satisfaction and a higher turnover intention than women nurses. In Japan, Minamizono et al. [32] analyzed 328 women nurses and inferred that the higher the burnout score, the higher the intention to change jobs. In other words, considering that the influencing factors of turnover intention vary by sex, increasing job satisfaction in men nurses and lowering burnout including emotional exhaustion in women nurses may reduce turnover intention.

This study showed that emotional labor was a significant factor influencing turnover intention, consistent with Bartram et al.'s [33] findings involving 183 nurses in Australia and 1160 nurses in China [18]. Emotional labor of eleven nurses in the front line against the COVID-19 pandemic in a Portuguese study was analyzed as five themes: challenges experienced by nurses in the front line, emotions experienced by nurses in service care, emotional responses of nurses and patients, emotional labor of nurses in the patient care process, and opportunities for development in the face of the emotional challenge required of nurses in combating COVID-19 [6]. Emotional labor can be overcome through an interpersonal or intrapersonal approach. Emotional support within the team facilitates the emotional labor's performance, which focuses on the patient and the relationship of care with emotional expression or touch, and self-focused emotional labor characterized by positive and adaptive emotional management [6]. In a previous study to verify the effect on nurses' emotional labor, resilience, and self-efficacy by applying an emotional coaching program for nurses, emotional coaching programs were useful for enhancing emotional labor management with 60 nurses

who worked at a general hospital [34]. Therefore, emotional labor programs and education to strengthen teamwork may be developed and applied to reduce nurses' intention to resign.

In this study, the relationship between positive psychological capital and turnover intention was not statistically significant, and positive psychological capital was not a factor that can influence turnover intention. These results are not consistent with a previous study in which psychological capital showed a significantly negative correlation with turnover intention for nurses [14]. One probable explanation is that people with high positive psychological capital would find better a working environment and job options any time when they are stressed out at work [35]; thus, it may not be an influence factor. Although our results differed from those of the previous study, psychological capital is essential for minimizing turnover intention [14]. Psychological capital intervention revealed significant improvements and remained stable over 1 month in the psychological capital [36]. In addition, nurse managers conducted psychological capital training courses and established a psychological capital enhancement system to reduce nurses' tendency to leave by improving their psychological capital level [14]. Therefore, psychological capital intervention may be applied to reduce nurses' turnover intention in organizational settings.

4.1. Study Limitations. This study has the following limitations: First, the study participants were from a single university hospital in South Korea, with more than 500 beds. Future studies should expand the research area for generalizability. Second, owing to the relatively high proportion of female nurses in the sample, the sex variable was controlled in the regression model to rule out the confounding effects; in future studies, sex should be controlled, or the sex ratio should be equal.

Moreover, given that nurses' turnover intention can affect not only the organization but also personal experiences or relationships with patients, developing a turnover intention-measuring scale that includes organization-related questions as well as questions about nurses' personal experiences and relationships with patients is necessary. However, despite these limitations, this study provides important findings concerning the factors that influence nurses' turnover intention, specifically the effects of sex and emotional labor.

5. Conclusions

This study reports the results of a descriptive survey to investigate the levels of emotional labor, positive psychological capital, and turnover intention in nurses caring for patients with COVID-19, clarifying the effects of emotional labor and positive psychological capital on turnover intention. Sex and emotional labor were identified as factors influencing turnover intention, with 9% explanatory power. Therefore, to lower the turnover intention of nurses in charge of patients with COVID-19, hospitals need to develop measures that can reduce their emotional labor.

5.1. Implications for Nursing Management. Increasing turnover intention in nurses implies decreasing nursing personnel; consequently, patients may not receive the proper nursing care. As a result of this study, nurses' emotional labor should be reduced to lower the turnover intention; this step can ultimately serve as a countermeasure to the shrinking workforce. Meacham et al. [9] said that high-involvement work practices (HIWPs) and individual resilience can buffer the negative effects of emotional labor on turnover intention of nurses. Based on this, it will be possible to increase HIWPs and develop resilience at the personal level to reduce emotional labor and consequently lower turnover intention. Also, the study findings are useful as foundational or applicable knowledge for developing programs designed to reduce the emotional labor of nurses caring for patients with COVID-19 not only in Korea but also internationally. To retain nurses, nurses and hospital managers should together implement programs aimed at reducing nurses' emotional labor and enhancing psychological capital (e.g., emotional coaching program and psychological capital intervention) and increase the number of nurses.

Background. Nurses play a critical role in the medical workforce during the COVID-19 pandemic while facing various difficulties and challenges. Grit, social support, and self-esteem are important psychosocial factors influencing job performance. However, few studies have explored the relationships among these factors in nurses. **Aim.** This study aimed to examine the association between grit and nurses' job performance during the COVID-19 pandemic and to explore the potential chain mediation through perceived social support and self-esteem. **Methods.** A cross-sectional survey design was employed. From January 2021 to May 2022, a total of 709 Chinese nurses in Chengdu and Kunming completed a web-based cross-sectional survey, which included standard assessments on grit, perceived social support, self-esteem, and job performance as well as Big Five personalities. The chain mediation model was tested using the PROCESS macro program in the SPSS software. **Results.** There was a moderate-to-large correlation ($r = 0.40$, $p < 0.001$) between grit and job performance in Chinese nurses. Furthermore, grit was indirectly linked to job performance through the chain mediating effect of perceived social support and self-esteem (all $p < 0.05$). These findings persisted even when Big Five personalities were included as additional controlling variables. **Conclusions.** This study reveals a stable link between grit and job performance among Chinese nurses and highlights the potential role of perceived social support and self-esteem in mediating this link. **Implications for Nursing Management.** Nursing managers can improve nurses' grit level and provide a supportive organizational environment conducive to enhancing self-esteem and thereby promoting their job performance.

1. Introduction

Accounting for the largest portion of the medical workforce [1], nurses play an increasingly important role in the healthcare system, especially highlighted by the COVID-19 pandemic [2]. The public labeled nurses as “heroes” because of their courage, bravery, commitment, resilience, and persistence during the pandemic [3]. Their work not only relates to the lives and health of patients but also plays a vital role in the management of public health and healthcare resources for society as a whole. Nevertheless, nurses had to face various difficulties and challenges such as working in high-risk environments, heavy workloads, insufficient

understanding and support from managers, and inadequate specialized training, which could result in burnout, lack of personal accomplishment, and lower efficiency and performance at work [4].

The complex situations during the pandemic exacerbated this dilemma and brought about organizational crises [5]. For instance, a survey by the American Nurses Foundation revealed that nearly 90% of the nurses reported staff shortages in their organizations and more than half of the respondents reported negative feelings such as being extremely stressed and undervalued during the COVID-19 pandemic [6], which may further lead to decreased personal performance at work [7]. In this context, probing the

psychosocial factors that may help nurses work effectively and improve performance addresses an important issue in nursing management and practice.

The active field of positive psychology offers novel insights into improving job performance [8], and one promising positive psychological construct is grit, a personality quality that can help explain why two individuals with the same level of intellectual ability are often observed to perform differently in a given field [9, 10]. Previous studies on different groups have indicated that grit positively impacts personal performance [10–13]. However, whether grit affects job performance in nurses and its underlying psychological mechanism remains unclear. Therefore, this study focused on the association between grit and job performance in nurses during the COVID-19 pandemic and explored the potential mediation mechanism underlying this association.

1.1. Grit and Job Performance. Grit, defined as perseverance and passion for long-term goals, is a nonintellectual trait essential to personal success and performance in various domains [10]. Gritty individuals are typified by working hard towards challenges with sustained efforts and interests despite failures, adversity, and plateaus [9, 10]. The well-established conservation of resources (COR) theory suggests that grit is an important personal resource that can facilitate goal achievement and promote personal growth and development [14, 15]. It is thought that individuals with high levels of grit are able to make better use of their abilities because they are less distracted by short-term goals and less discouraged by failures and setbacks that are commonly encountered in many performance areas [16], which can lead to better performance in those areas. Numerous empirical studies have demonstrated the positive effect of grit on personal performance in a wide range of fields covering students' academic performance [13, 17], employees' job performance [11, 18, 19], performance in military [20], and sports [21]. In particular, grit has been found to predict both the academic and clinical performance of nursing students after controlling for potential confounders including the year of study and demographic factors [13]. Despite the well-documented relationship between grit and performance in these areas, the impact of grit on job performance in nurses has not been robustly determined. Moreover, grit has been proposed as an essential trait of nurses during a disaster to enable them to complete the arduous tasks required [22]. Hence, the first aim of this study was thus to determine the association between grit and job performance in a sample of Chinese nurses during the COVID-19 pandemic.

1.2. Grit, Perceived Social Support, Self-Esteem, and Job Performance. Understanding how grit affects job performance is important for nursing managers developing effective strategies to improve nurses' job performance. Some have argued that goal pursuit and attainment are outcomes of interaction between personal resources and the environment [23, 24]. A qualitative study found that the social support system (e.g., family, friends, significant others,

superiors, or colleagues) is a major contributor of grit in achieving personal and work goals in Asian graduate students [25]. When people feel supported by others in their pursuit of long-term goals, they may display greater levels of perseverance, resulting in improved performance [25]. In return, gritty individuals are more likely to attract social support due to their unwavering dedication and passion, which may exert a positive effect on performance [24]. It has been demonstrated that perceived social support is more predictive and functional than received social support [26], even though they are highly correlated [27]. Perceived social support is defined as the perception of the available support from one's social networks [26]. Previous studies have found positive correlations between grit and perceived social support in adolescents [28] and nurses [29]. Moreover, there are also positive associations between perceived social support and nurses' task performance [30], particularly during the COVID-19 pandemic [31]. According to the Job Demands-Resources (JD-R) model [32], social support is a form of job resources provided to employees to deal with the job demands which can help them stay healthy and is therefore closely related to job performance [33]. Low levels of perceived social support have been reported to cause emotional exhaustion in working women during COVID-19 which may relate to the job performance [34]. On the other hand, it is suggested that certain personalities, e.g., grit, can help employees cope with job demands and increase their job resources, which in turn can lead to better job performance [35]. Hence, in investigating the relationship between grit and job performance, perceived social support can be regarded as an important mediator at the external influence level [25].

Self-esteem is another personal resource that helps motivate and facilitate goal attainment in COR theory, which has been shown to be an important indicator of personal performance [36–38]. Self-esteem refers to an individual's overall evaluation of their own worth, competence, and value [39]. High self-esteem stimulates self-potential [40] and is associated with many positive behaviors and outcomes such as enhanced learning motivations [41], less antisocial behavior [42], higher life satisfaction [43], and better physical and mental health [42, 44]. Importantly, self-esteem is one of four dispositional traits (i.e., self-esteem, generalized self-efficacy, locus of control, and emotional stability) that are significantly related to job satisfaction and job performance according to Judge, Locke, and colleagues' theory of core self-evaluations [45] and exhibits the highest correlation with job performance among the four traits [37]. Korman [46] self-consistency theory suggests that individuals with high self-esteem will perform effectively in order to maintain a positive self-image. On the other hand, prior research suggests that self-esteem shows a medium-sized association with grit [40, 47], and this may be related to the possibility that during the process of pursuing long-term goals with passion and persistence, gritty individuals can gain a better understanding about themselves and be more satisfied with themselves [48, 49], which may contribute to higher levels of self-esteem and better job performance. Thus, self-esteem may be an internal

factor that mediates the relationship between grit and job performance.

With respect to the relationship between perceived social support and self-esteem, it has been argued that social support is a critical component for maintaining individuals' self-esteem [31], while self-esteem can reflect the quality of interpersonal relationships based on the sociometer hypothesis [50, 51]. Several studies have found a positive correlation between perceived social support and individuals' self-esteem [43, 52, 53]. A recent study shows that the failure to receive online social support during COVID-19 can result in reduced self-esteem and increased loneliness [54]. According to the sociometer theory, when one's relational deficiencies are detected, self-esteem will be negatively affected in an automatic, unconscious way as an "internal monitor" [55]. By contrast, high perceived social support from family, friends, and significant others can enhance university students' self-esteem, promote their academic achievements, and mitigate their emotional exhaustion [47]. Furthermore, self-esteem is found to mediate the relationship between perceived social support and academic achievement [48, 56] as well as the intention to stay in nurses [57]. Previous studies have indicated that perceived social support and self-esteem sequentially mediate the association between Internet use and loneliness [54, 58]. Based on the above findings and theories, it is plausible to explore the chain mediation of perceived social support and self-esteem in the relationship between grit and nurses' job performance. The second aim of this study was thus to examine the indirect effect of grit on job performance with perceived social support and self-esteem as the intervening variables.

1.3. The Current Study. This study aimed to reveal the relationship between grit and nurses' job performance and particularly examine the sequential mediating roles of perceived social support and self-esteem in this relationship. The present study extends previous research in several respects. First, prior investigations into the link between grit and performance focused mainly on the academic and other professional domains [11, 17, 21], whereas few studies have tested it in nurses [59, 60]. Given the large number of Chinese nurses (i.e., 4.7 million as of 2020) and their heavy workloads and unprecedented pressure in the COVID-19 pandemic [61], it is essential to explore how Chinese nurses' grit influences their job performance. Second, although previous studies and theories suggest that social support and self-esteem may play a mediating role in the link between grit and job performance, no research has directly examined the mediating effect, especially the sequential mediating effect, of perceived social support and self-esteem between grit and job performance. Third, previous research generally did not control for similar psychological constructs such as Big Five conscientiousness when examining the relationship between grit and performance, which may be a reason for the inconsistent results of previous studies [10, 16]. Therefore, this study used well-validated measurements to investigate the intercorrelations among grit, job performance, perceived

social support, self-esteem, and Big Five personality traits in a large population of Chinese nurses ($n = 756$) during the COVID-19 pandemic. Then, we constructed a serial mediation model to test the chain mediating effects of perceived social support and self-esteem in the grit-job performance association and moreover tested the specificity of the results by controlling for effects of Big Five personalities in this model given that Big Five traits have been shown to relate robustly to grit [48] and job performance [62]. These analyses can help elucidate the mechanism and specificity of the impact of grit on nurses' job performance. Based on previous research, we proposed the following hypotheses:

Hypothesis 1: Grit is significantly and positively related to job performance in nurses

Hypothesis 2: Perceived social support mediates the relationship between grit and nurses' job performance

Hypothesis 3: Self-esteem mediates the relationship between grit and nurses' job performance

Hypothesis 4: Perceived social support and self-esteem sequentially mediate the relationship between grit and nurses' job performance

2. Methods and Materials

The present study was implemented using a cross-sectional survey design. We adhered to Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) guidelines and methodology in reports of cross-sectional studies (see Supplementary Information: Table S1).

2.1. Participants and Procedures. A total of 756 nurses from several hospitals in Chengdu and Kunming in Southwest China through convenience sampling participated in this study between January 2021 and May 2022. Forty-seven participants who failed to pass the bogus items (e.g., I have five fingers on my left hand) that had only one correct answer in the survey [63] were excluded from analyses, resulting in a final sample of 709 respondents (643 females, age = 18–55 years, mean age = 31.74 ± 7.38 years) with an effective response rate of 93.78% [64]. The current sample size was far greater than the estimated sample size ($n = 207$) to detect medium-sized effects based on standard power analysis while considering 20% of incomplete surveys [65, 66]. The inclusion criteria were (a) obtaining a professional qualification certificate for nurses in the People's Republic of China, (b) having at least 1 year of experience in clinical nursing or nursing management, (c) having no previous or current diagnosis of mental illness or drug or alcohol dependence, and (d) having the skills to complete the questionnaires online. Trainee nurses, standardized training nurses, and nurses who were unable to complete the survey were excluded. Notably, none of the participants were infected with COVID-19 proved by their nucleic acid testing report.

The questionnaires were distributed through online recruitment to designated investigators in each hospital who had been trained by the researchers, in compliance with quarantine guidelines to mitigate the spread of COVID-19 infection. After signing an online informed consent to their voluntary participation in the study, each participant completed the questionnaires independently under the guidance of the investigator. The investigators needed to answer questions for participants based on uniform guidelines. The survey was anonymous, and data confidentiality was assured. All measures were written in simplified Chinese. This study was approved by the local Ethics Committee of West China Hospital of Sichuan University.

2.2. Measures

2.2.1. Short Grit Scale. The scale is a self-report instrument originally developed and validated by Duckworth and Quinn [11] to measure grit. It includes two subscales: consistency of interest (e.g., “New ideas and projects sometimes distract me from previous ones”) and perseverance of effort (e.g., “I finish whatever I begin”). Each subscale consists of four items, and participants were required to rate their agreement to each item on a five-point Likert scale ranging from 1 (not like me at all) to 5 (very much like me). The Chinese version of this scale was translated and validated by Li and colleagues (2018) using a back-translation process, which proved to have good reliability and validity among different populations [67–69]. All items in the consistency of interest subscale are negatively phrased, and the item responses are reverse-coded for scoring. A total score was obtained by summing the subscale scores, with higher total scores indicating a higher level of grit. Given that previous studies have demonstrated that the total score was a better predictor of personal success in the most demanding domains than either factor alone [11, 70], we focused on the total score in the current analyses. Cronbach’s α of this scale in this study was 0.75, indicating adequate internal reliability.

2.2.2. Task Performance Scale. We used the five-item Task Performance Scale for assessing in-role job performance [71, 72]. Participants were asked to indicate the extent to which they agreed or disagreed on a seven-point Likert scale (1 = “strongly disagree” to 7 = “strongly agree”) with the statements such as “I can always complete the duties specified in my job description.” Task performance is represented by summing the scores; the higher the score, the better the task performance. The scale showed acceptable psychometric properties in Chinese samples [67, 73]. In this study, Cronbach’s α was 0.96, indicating satisfactory internal reliability.

2.2.3. Multi-Dimensional Scale of Perceived Social Support. The scale was used to measure an individual’s perception of social support from various sources, i.e., significant others, family, and friends [74]. The scale consists of 12 items, e.g., “My family really tries to help me.” Participants rate their

agreement with each statement using a seven-point Likert scale ranging from 1 (very strongly disagree) to 7 (very strongly agree). The scores from the items are summed to provide a total score for each dimension and an overall score for perceived social support. The scale has shown good reliability and validity in Chinese populations [58, 75]. As in previous studies [48, 76], the present study only focused on the overall score in the analyses. In the current study, Cronbach’s α of this scale was 0.94, indicating satisfactory internal reliability.

2.2.4. Rosenberg Self-esteem Scale. The scale was used to assess self-esteem [39], which consists of 10 items measuring an individual’s overall evaluation of himself/herself. Participants are asked to indicate their level of agreement or disagreement with each statement using a four-point Likert scale ranging from 1 (strongly disagree) to 4 (strongly agree). It includes items such as “I am able to do things as well as most other people.” Total scores can range from 10 (lowest self-esteem) to 40 (highest self-esteem). The scale has good reliability and validity in Chinese populations [56, 77]. In this study, Cronbach’s α was 0.88, indicating adequate internal reliability.

2.2.5. Big Five Inventory. To exclude the potential effects of general personalities on the associations among grit, perceived social support, self-esteem, and job performance, we used a 44-item Big Five Inventory to evaluate the personality traits including openness, agreeableness, conscientiousness, extraversion, and neuroticism [78]. Each item is assessed on a five-point Likert scale ranging from 1 (strongly disagree) to 5 (strongly agree). The scale has been translated and validated across different countries and cultures [79, 80]. The Chinese version has demonstrated adequate reliability and validity [79, 81]. In this study, Cronbach’s α s of the five dimensions were 0.78 (openness), 0.72 (agreeableness), 0.80 (conscientiousness), 0.72 (extraversion), and 0.78 (neuroticism), indicating adequate internal reliability.

2.3. Data Analysis. All behavioral data were analyzed using the statistical software SPSS 25.0 (SPSS Inc., Chicago, IL, USA). There are no missing data due to the settings of the web-based survey. First, to examine the effect of common method deviation that may arise from the measurement method regarding self-reported scales and can lead to inaccurate results [82, 83], Harman’s single-factor tests were conducted on all items of the four scales [84]. The participants’ sociodemographic characteristics and major variables were analyzed as descriptive statistics (i.e., mean and standard deviation (SD)). Pearson correlation analyses were performed to investigate the bivariate correlations among the measurements.

To test the mediating effects of perceived social support and self-esteem in the relationship between nurses’ grit and job performance, we used a bias-corrected bootstrapping method with PROCESS macro implemented in SPSS [85]. Mode 6 was chosen for the serial mediation analysis. We

tested our hypothesized chain mediation model in which grit (X) increases perceived social support ($M1$), which affects self-esteem ($M2$), which in turn leads to higher job performance (Y), while controlling for sex, age, education, professional title, marital status, and working years (as well as Big-Five factors). Bias-corrected confidence intervals for the indirect effect were calculated using 5,000 bootstrapped samples. This analysis also tests each mediator separately to assess the contribution of the simple mediations to the indirect effect on the relationship between X and Y . An empirical 95% confidence interval that did not contain 0 signified that the mediating effect was statistically significant [86].

3. Results

3.1. Common Method Bias. The results indicated that there were seven eigenvalues whose values exceeded 1 and the variance explained by the first eigenvalue was 33.37% (<40%), indicating that this study did not suffer from serious methodology bias [84].

3.2. Descriptive Statistics and Correlation Analysis. Table 1 presents the frequency/percentage or mean, SD, and range for sociodemographic characteristics. Most of the participants were females (643 females, 90.7%), and the average age for all participants was 31.74 ± 7.38 years old. 398 nurses (56.1%) had a bachelor's degree; 483 nurses (68.1%) were married; 366 nurses (51.6%) had a primary title; and the average total work experience was 10.67 ± 8.12 years.

Descriptive statistics and bivariate correlations for all measurements are shown in Table 2. As expected, higher grit was positively associated with higher perceived social support, self-esteem, and job performance ($ps < 0.001$). Perceived social support, self-esteem, and job performance were also intercorrelated ($ps < 0.001$). Moreover, grit was associated with all Big Five personality traits ($ps < 0.001$).

3.3. Chain Mediation Model Analysis. A serial mediation analysis was conducted to test the effect of perceived social support and self-esteem as multiple sequential mediators in the indirect relationship between grit and job performance in nurses via Model 6 in SPSS macro. Grit and job performance were entered as the independent (X) and dependent (Y) variables, respectively; perceived social support ($M1$) and self-esteem ($M2$) were added as mediators; sex, age, education, professional title, marital status, and working years were included as covariates.

As shown in Table 3 and Figure 1, the total effect of grit on job performance ($\beta = 0.39$, $p < 0.001$) decreased when the mediators were included in the model ($\beta = 0.14$, $p < 0.001$), suggesting that the effect of grit on job performance was partially mediated by perceived social support and self-esteem. Bootstrap estimation procedure ($n = 5000$) indicated that the indirect effects for this model were statistically significant (indirect effects = 0.55, $SE = 0.03$, 95% CI = [0.21, 0.31], accounting for 64.1% of the total variance; Table 3). The indirect effects were generated through three

TABLE 1: Sociodemographic characteristics of the participants.

Variable	Mean \pm SD (range) N%
Sex	
Female	643 (90.7%)
Male	66 (9.3%)
Age (years)	31.74 \pm 7.38 (18–55)
Educational level	
Graduate degree	4 (0.6%)
Bachelor degree	398 (56.1%)
College degree	270 (38.1%)
Secondary vocational degree	37 (5.2%)
Marital status	
Married	483 (68.1%)
Unmarried	198 (27.9%)
Divorced	26 (3.7%)
Widowed	2 (0.3%)
Professional title	
Vice senior	10 (1.4%)
Intermediate	170 (24.0%)
Primary	366 (51.6%)
None	163 (23.0%)
Length of nursing work (years)	10.67 \pm 8.12 (1–39)

Note. N, number; SD, standard deviation.

paths: Path 1 consisting of grit \rightarrow perceived social support \rightarrow job performance (indirect effect = 0.09, 95% CI = [0.05, 0.14]), Path 2 consisting of grit \rightarrow self-esteem \rightarrow job performance (indirect effect = 0.11, 95% CI = [0.07, 0.15]), and Path 3 consisting of grit \rightarrow perceived social support \rightarrow self-esteem \rightarrow job performance (indirect effect = 0.05, 95% CI = [0.03, 0.07]), which were all statistically significant. Hence, there is a chain mediation of social support and self-esteem as well as separate mediating effects of each on the relationship between grit and job performance in nurses.

3.4. Specificity of Findings. To test the specificity of the findings, we furthermore added Big Five personality traits, i.e., openness, agreeableness, conscientiousness, extraversion, and neuroticism, as additional controlling variables in the serial mediation model. The analysis yielded robust results (see Supplementary Information: Table S2 and Figure S1).

4. Discussion

In the present study, we investigated the relationship between grit and job performance in a sample of Chinese nurses during the COVID-19 pandemic, as well as the mediating role that perceived social support and self-esteem played in this relationship. The results revealed that grit not only directly influenced job performance but indirectly affected job performance through perceived social support and self-esteem separately and sequentially, and these findings were independent of Big Five personalities, all of which may provide an insightful understanding of underlying mechanisms that explain the influence of grit on job performance.

The positive relationship between grit and job performance found in the current sample is consistent with the

TABLE 2: Descriptive statistics and bivariate correlations of study measures.

Measure	Mean \pm SD	Range	1	2	3	4	5	6	7	8
1. Grit	27.03 \pm 4.14	17–40	—							
2. Perceived social support	66.23 \pm 10.69	21–84	0.41	—						
3. Self-esteem	31.03 \pm 4.30	16–40	0.50	0.53	—					
4. Job performance	29.20 \pm 4.21	5–35	0.40	0.46	0.52	—

Standardized regression coefficients were displayed in the path diagram; c , total effect; c' , direct effect; *** $p < 0.001$, ** $p < 0.01$. Sex, age, education, professional title, marital status, and working years were treated as covariates in the model.

findings of previous studies on this relationship [18, 19, 60]. Particularly, the present study verified this association in a large population of Chinese nurses during the pandemic even after controlling for the effects of Big Five personality traits, which extends the generalizability, specificity, and ecological validity of previous findings on this link. This finding agrees with the well-established COR theory, which proposes that grit is one of the personal resources linked to work goal progress [14, 24]. Prior research has shown that grit is associated with less burnout in healthcare professionals and students [87, 88], which facilitates long-term work and stability of nursing staff [88]. The increased job demands (e.g., surges in patient volume) during the pandemic led to healthcare professionals' burnout and exhaustion [2], which is found to impact objective and subjective work performance in nurses [89]. High levels of

grit may protect nurses from burnout and persevere through challenges [90] and therefore affect nursing job performance. Notably, the grit-job performance association was independent of Big Five personality traits, which supports the specificity of the current findings. Big Five traits have long been found to predict success and achievements [11, 78, 91]. In particular, Big Five conscientiousness is strongly correlated with grit and is a robust predictor of job performance [11, 62], yet Grit-S predicts achievement outcomes over and beyond conscientiousness and other Big Five traits [10, 11, 48, 92], which aligns with the present finding. Our study provided further evidence that grit captures a unique aspect of perseverance and passion that is distinct from the traditional personality dimensions, which appears to specifically predict job performance in nursing contexts. Nevertheless, based on the too-much-of-a-good-

thing (TMGT) framework in management proposed by Pierce and Aguinis [93], the beneficial role of psychological resources (e.g., grit) may be reversed into a negative factor of performance when grit is at a very high level; thus, future studies are needed to test the curvilinear relationship between grit and nurses' job performance [24].

The finding that perceived social support and self-esteem separately mediate the relationship between grit and job performance in nurses supports the JD-R model and COR theory. According to the JD-R model, social support is a type of job resource and grit and self-esteem can be deemed as personal resources that ultimately improve the job performance of working people [33], and external supports supplement internal motivation to increase their ability to perform well in their jobs. Hobfoll's [14] COR theory posits that people tend to acquire, maintain, and avoid losses of valuable resources, including objects (e.g., food), environmental conditions (e.g., interpersonal relationships), personal characteristics (e.g., grit and self-esteem), and energies (e.g., time) that serve as means for goal attainment. The COR theory further integrates the impact of perceived social support as a moderator of the relationship between grit and goal progress [24]. Research shows that gritty nurses can improve their meaning in life through perceived social support [29]. It may be that social support provides emotional assistance to help gritty individuals cope with workplace stress and adversity as they continue to pursue long-term goals, which is conducive to maintaining their performance levels. In particular, gritty nurses tend to feel a high level of social support because they use more positive coping strategies to deal with stress such as seeking and appreciating social support [94], which may enhance their perceived social support. Consequently, nurses with a high level of perceived social support are less likely to experience burnout and more likely to have increased overall well-being, which can lead to improved job performance as they are better able to engage in their work even during the pandemic [30, 95]. On the other hand, self-esteem, as a core self-evaluation trait, has been demonstrated to show the highest correlation with job performance as compared to other core traits [37] and is also positively related to grit [40, 43, 96]. Prior research has found self-esteem as a mediator in the link between grit and employees' life satisfaction [47]. The current study extends previous studies by revealing an indirect effect of grit on nurses' job performance through self-esteem. The mediating role of self-esteem in the grit-job performance relationship may be because gritty nurses may receive more positive feedback and reinforcement due to their persistence and passion, which can further enhance their self-esteem and encourage them to continue to achieve high job performance [48, 49].

The most important contribution of this study is elucidating the chain mediating effect of perceived social support and self-esteem on the relationship between grit and nurses' job performance. High levels of grit are associated with the perception of greater perceived social support, which in turn fosters higher self-esteem and ultimately improves nurse performance, highlighting the potential usefulness of social support as an external source and the

resulting self-esteem as a personal resource to improve job performance in gritty people. According to the sociometer theory [55], self-esteem is an internal measure to monitor one's interpersonal relationships and success. Feeling supported by others can contribute to individuals' overall sense of self-worth, value, and confidence in their abilities, whereas a lack of support from social relations makes individuals feel devalued and rejected [97], which can lead to negative self-evaluations and low self-esteem. Studies found that perceived organizational support can significantly increase nurses' self-esteem [53, 98]. Social support has long been recognized as an important coping strategy during times of crisis, and reduced social support is associated with nurses' burnout [4] and traumatic stress [99] during the COVID-19 pandemic. Thus, during a time full of stress and uncertainty, gritty nurses might actively seek and utilize their social support networks to maintain a high perception of social support, which can boost their self-esteem and in turn lead to better job performance during the pandemic.

5. Limitations of the Study

This study has some limitations. First, the study used a cross-sectional design which did not permit inference about the causality relations; thus, caution is needed to interpret the current finding, and the feasibility of the findings for use in nursing management warrants further investigation. Future studies may also test the mediating models using a longitudinal design tracking the changes of these variables over time to draw robust conclusions about causality [100]. Second, the data were collected only through self-report instruments. Although these questionnaires were selected for their good reliability and validity, self-report measures are vulnerable to biases, such as social desirability; future studies should incorporate more objective evaluations [101] and experimental tasks to precisely measure these variables. Third, the present study only measured perceived social support from family, friends, and significant others and did not assess perceived organizational support [98], which may play a particularly important role in the intensive work during the pandemic [102]. Fourth, this study only focused on Chinese nurses sampled from several local hospitals in Southwest China, and future studies need to expand the survey area (e.g., other regions of China or other countries) to improve the generalizability of the findings. Finally, previous neuroimaging studies have identified the neural substrates of grit [92, 103] and determined the neuroanatomical basis linking perceived social support to self-esteem [104], yet how these brain markers predict job performance remains uninvestigated; future studies are invited to explore the neural mechanisms underlying the associations among these variables in the framework of organizational cognitive neuroscience [105, 106].

6. Implications for Nursing Management

Our findings have critical implications for nursing management. The chain mediation provides new insights into enhancing grit to improve job performance. Specifically, at the organizational level, nursing managers should

implement personal education about the importance of grit in nurses, which can help them cope with stress and challenges when facing obstacles and difficulties at work. Second, it is necessary to provide unconditional organizational support to nurses and build support teams to expand their knowledge and skills as well as share their experiences and emotions, which may be an essential job resource that helps form positive feelings and evaluations of themselves [54] so as to increase their job performance. Moreover, psychological training programs aiming at fostering grit and self-esteem are suggested to be developed and adopted, which may also be conducive to nurses' job performance, especially during a crisis like the COVID-19 pandemic.

7. Conclusions

The current study investigated the association between grit and nurses' job performance during the COVID-19 pandemic and explored the chain mediation through perceived social support and self-esteem. The results showed that grit not only directly affects job performance but also has indirect effects through perceived social support and self-esteem, both independently and sequentially. These findings were not affected by Big Five personalities as well as sociodemographic characteristics, showing a specific nature to some degree. Our study has important implication for nursing management to improve nurses' job performance.

Data Availability

West China Hospital of Sichuan University has an institutional commitment to data sharing. To get access to the data and comply with the terms of our research ethics committee approval, an application to the corresponding author will be required, specifying the geographical extent of sharing.

Ethical Approval

This study involving human participants was approved by the local Ethics Committee of West China Hospital of Sichuan University (approval number: 2020HXBH092). All participants were asked to read and sign an online informed consent form before the study.

Disclosure

The funding sources had no involvement in the study design, data collection and analysis, results' interpretation, writing, or decision to publish the paper.

Conflicts of Interest

The authors declare that they have no conflicts of interest.

Acknowledgments

The authors sincerely thank Dr. Graham J. Kemp for providing language help and all nurses who participated in this study. This work was supported by the National Natural

Science Foundation of China (Grant no. 31800963) and the Key Research and Development Program of Sichuan Province (Grant no. 2023YFS0084).

Background. Nurses are one of the largest and costliest groups in healthcare organizations; therefore, it is important to comprehend their scope of practice. **Aim.** To contribute to the improvement of nursing resource management in medical-surgical and Intensive Care Units by identifying factors that influence the scope of nursing practice. The hypothesis was that the activities carried out by nurses in medical-surgical units and intensive care units are influenced by individual and job-related factors, with job characteristics having an additive and moderating effect on individual characteristics. **Materials and Methods.** Cross-sectional correlational design to test the relationship between the individual and job characteristics on the nursing scope of practice measured by the Actual Scope of Nursing Practice (ASCOP) questionnaire. The sample consisted of 270 nurses. Linear mixed effects models analysis (LME) was used with the aleatory effect of the intensive care unit (ICU). **Results.** Belonging to the ICU decreased the scope of practice of nurses. We found a statistically significant effect of psychological demand, practice environment, role ambiguity, and growth need strength on the scope of nursing practice. The models explained a variance up to 24%. **Conclusions.** Although the survey results revealed the existence of broader scope of practice levels in Spanish hospital units than in the original Canadian study, the use of scope of nursing practice remains suboptimal. Higher levels on the psychological demand, the practice environment and in the individual growth need strength were related with a broader scope of practice. Otherwise, role ambiguity negatively affected the scope of practice. **Implications for Nursing Management.** This article provides an analysis of the impact of individual and job-related characteristics on the nursing scope of practice. It serves as a valuable resource for both managers and nurses, offering insights to improve nurses' working conditions and obtain more efficient workforces.

1. Introduction

In healthcare organizations, nursing human resources represent one of the most important groups because they are one of the largest and most expensive staff for healthcare services [1]. In addition, due to the current world situation, healthcare systems are facing a nursing staff shortage situation. There are insufficient numbers of nurses and that can directly impact patient outcomes [2]. McGahan et al. [3] have linked nursing human resources with a considerable improvement in patient outcomes, while it has been shown

that a higher nursing ratio or lower staffing levels may compromise patient safety [4] and their association with adverse events as well as mortality rates in medical and surgical inpatient care [5].

Numerous studies provide evidence of the significant impact of effective nursing management on healthcare organization outcomes and address the sustainability of nursing services, that it is "strongly influenced by the availability of productive nurses" [6]. Even though the lack of nurses is a serious problem in healthcare administration, it can be an ideal period to analyze the efficiency of nursing

human resources and the use of their full range of skills. Based on this analysis improvements in their work conditions may be proposed, and measures to ensure that they work as effectively as possible, and they provide continued and high-quality services can be adopted.

However, beyond the number of nurses working in each unit, it is important to consider the specific functions performed by these nurses. In this regard, a study developed by Gravling and Phoenix [7] confirmed that nurses stop performing nursing care while they carry out other tasks that are not within their competence. Therefore, it is imperative not only to examine coverage levels of nurses and their education qualifications in relation to the functions they are educated for and competent to carry out but also to analyze their specific functions and responsibilities, what is called "scope of nursing practice."

The "actual scope of practice" refers to the professional activities carried out in a setting by nurses, as opposed to those that are expected to be optimal [8]. According to White et al. [9], the optimal scope of nursing practice, which is associated with the nurse's education level, job title, and experience, differs from the actual scope of nursing practice, which is influenced primarily by organizational context and employer policies.

In the context of a study carried out in the United States, the recommended strategies to reduce the cost generated by nurses, same as those focused in the improvement of quality of care, should be designed to ensure that nurses allocate the required time to patients and reduce activities that do not add additional value [10]. Non-value-added care is the care that is either unimportant, potentially harmful, or could be performed at a similar cost by less-trained or less costly staff.

Furthermore, the study developed by Déry's et al. [8] concluded that different levels in the scope of practice can influence not only healthcare costs but also patient outcomes and the satisfaction of nurses. These authors developed the Actual Scope of Nursing Practice (ASCOP) model, which explains how individual and job characteristics have a direct impact on the functions performed by nurses and on their job satisfaction [11].

The model was developed defining linkages between factors influencing the scope of nursing practice, where the personal characteristics such as growth need strength, education level, experience level and autonomy, psychological demand, and role stressors as job characteristics [8]. The model has been further evolved and different updates have been published defining the different variables. The same researchers independently studied the influence of the level of education and they concluded that nurses with higher levels of education were found to be those who perform the more complex nursing activities, both those involving higher management skills and those involving more committed tasks such as staff supervision [12]. In addition to educational level, growth need strength was found to be significant in predicting scope of nursing practice, while job autonomy, psychological demands, and role stressors were also associated as predictor variables [13].

The authors' latest update was conducted at a mother-infant hospital in Quebec. It included the incorporation of

missed care and an analysis of organizational indicators [14]. Our proposal was to validate the same model in the Spanish population, so we considered including the variables used in the original framework. We did not include analysis of missed care, but we added some organizational factors, which we explain below.

Building upon the ASCOP model, the present study examined two new variables: nurses' evaluations of their practice environment and nurse-to-patient ratios. The practice environment consists of the organizational features of work that may facilitate or hinder nursing practice. This includes factors such as nurse-physician relationships, leadership and support for nurses, nurse involvement in hospital affairs, nursing's basis for quality care, and perceptions of resource provision and adequacy of resources [15]. On the other hand, nurses per patient ratio are a crude indicator of the nursing time available on a unit and refers to the number of patients nurses can care for simultaneously. The rationale for including these factors is based on their repercussion on both patients safety outcomes and the work factors of the nurses themselves. Numerous studies show that nurse staffing and the quality of nurses' work environment are associated with the quality of patient care. Hospitals with poor work environments present an increase of adverse outcomes but also lower levels of nurses' productivity [16]. Therefore, this variable, which not only impacts on patient outcomes, is particularly important in our study because of its direct influence on nurses' productivity, consequently affecting their scope of practice and their intention to leave their job [17].

When examining the factors that determine the scope of practice, the nurse-to-patient ratio was considered essential because, as Clarke argued, staffing levels directly affect the amount and quality of work that nurses are able to offer each patient [18]. Moreover, the same paper highlighted the relevance of studying the possible correlation between hospital work environment and staffing. Along the same line, Aiken et al. [19] have already worked on the implications of nurse staffing for recruitment, retention of nurses, and quality of care, suggesting that those job positions with better work environments were associated with a decrease in burnout and job dissatisfaction. This made the study of the working environment indispensable for our analysis. The framework for the current study is shown inside the die-cut box of Figure 1.

As shown in the area marked with the pointed box in Figure 1, our study focuses on how personal and work characteristics affect the scope of nursing practice, in addition to the effect that individual characteristics can have on work characteristics. In recent years, nursing managers are facing increasing difficulties in expanding nursing staff. This is due to a variety of factors, such as financial shortages, the underutilization of nurses, and the increasing cost generated by the new health needs of the population. Based on the above conceptual framework, our study seeks to find an approach that can guide nursing leaders to apply the necessary adjustments in nursing teams and to consider how to facilitate their working conditions to improve their productivity.

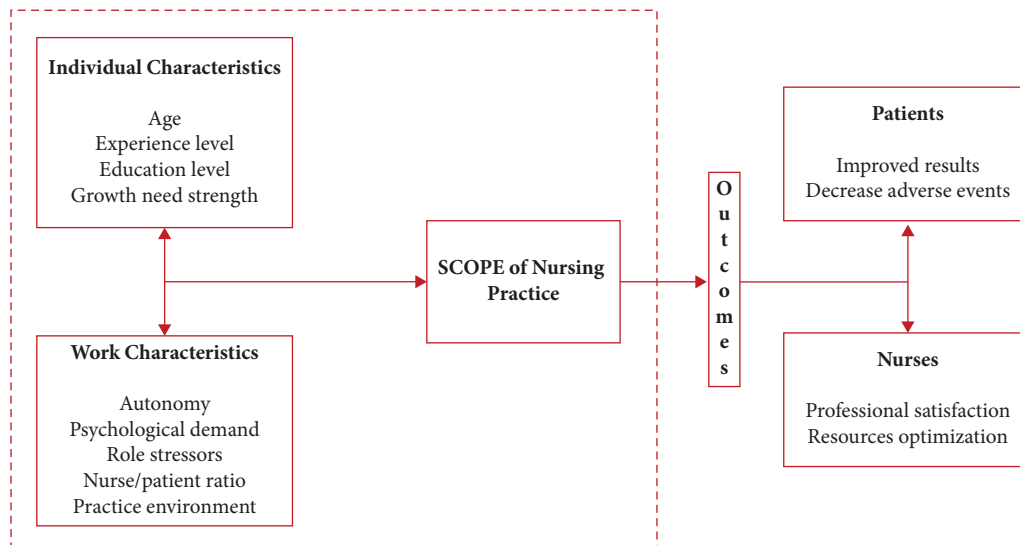

FIGURE 1: Redrawn conceptual framework based on ASCOP model [8].

Regarding the hospitalization units, where the study took place, it is worth mentioning the particularities of the ICUs for nurses working in these settings. Working in such a specialized environment like the ICU can be particularly stressful for the staff [20], and several studies have demonstrated a connection between ICU nurses and increased level of burnout [21].

Furthermore, it should be highlighted that the nature of nursing workforce in Spain differs from the characteristics of the professional structure in other countries. In the Spanish context, the access to jobs in the different health services or fields is the same for all registered nurses regardless of their level of training, except in special cases such as mental health nurses and midwives, which are not included in the study. The nurses working in the hospital hold a university degree to access the nurse jobs and maintain the same level of qualification throughout their careers, even as they pursue training through postgraduate, master's, and doctoral programs.

Considering the specific characteristics of nursing job in Spain, as well as the knowledge gap in this field, the main aim of this study is to contribute to the improvement of nursing resource management in medical-surgical and intensive care units by identifying factors that influence the scope of nursing practice.

Given the reasons described above and based on the following hypotheses, "the activities carried out by nurses in medical-surgical units and ICU are influenced by individual and job-related factors, with job characteristics having an additive and moderating effect on individual characteristics," these research questions motivated the study: Q1: "How do nurses' individual characteristics and the nature of their work affect their professional activities?" Q2: "Are the individual and job characteristics determinants of the scope nursing scope of practice?" Q3: "What is the relationship between the individual characteristics of nurses and the characteristics of their work? And how do these factors affect the activities they engage in within their profession?"

2. Materials and Methods

2.1. Design. A cross-sectional design [22] was used to test the relationship between the individual and job characteristics of the nurses and the outcome variable, nursing scope of practice.

2.2. Setting. This study was performed in 29 adult hospitalization units (24 general medical and surgical units and 5 intensive care units) of the 3 main public hospitals in a Spanish region of "Region blinded for review."

2.3. Sample. The following parameters were used to calculate the sample size: type I error of 0.05, type II error of 0.2 (power of 80%), and minimum detectable effect for a moderate intensity relation between the variables of interest 0.35. In addition, a 5% nonresponse rate was considered. The resulting size was penalized to contemplate the rest of the variables of the study, as suggested by Hsieh et al. [23], estimating a coefficient of determination for all of them of 0.32, according to the original study results [24]. Considering all these factors, a simple sample size of 270 subjects was calculated.

Convenience sampling was used. The total of 402 nurses working in clinical roles or in direct patient care were invited to participate in the study, and workers with less than 6 months of service at the institution were excluded. The first 270 nurses who responded to the questionnaire were chosen from among all eligible nurses.

2.4. Variables and Instruments. An online questionnaire was developed including the different measurement instruments to assess the study's variables of interest (Table 1).

The nursing scope of practice, or main variable, refers to the set of functions and responsibilities carried out by nurses, in relation to their competence and experience.

TABLE 1: Variables and the measurement instruments with their characteristics.

Variable	Questionnaire	N. items	Scale (Likert)
Nursing scope of practice	ASCOP questionnaire [25]	20	1-6, "never" to "always"
Age, years of experience, education level, nurse-to-patient ratio, unit	Demographic questionnaire		
Growth need strength "would like"	Job diagnostic survey (2 subscales) [26]	11	4-10
"Job choice"		12	1-5
Autonomy and psychological demand	Job content questionnaire [27]	18	1-4, "strongly disagree" to "strongly agree"
Role ambiguity and role conflict	Role ambiguity scale [28]	14	1-7, "strongly disagree" to "strongly agree"
Role overload	Role overload questionnaire [29]	3	1-5, "strongly disagree" to "strongly agree"
Practice environment	Pes-NWI [30]	32	1-4, "strongly disagree" to "strongly agree"

It was measured with the ASCOP questionnaire [24], in its Spanish version [25]. The original questionnaire evaluates the frequency of activities carried out by nurses in six areas of practice: assessment and care planning, teaching of patients and families, communication and care coordination, integration and supervision of staff, quality of care, and patient safety and knowledge updating and utilization. The internal consistency of the original Canadian instrument showed Cronbach's alpha of 0.89 [24]. In this study, the Spanish adaptation of the ASCOP questionnaire was used, which includes 20 items and two main dimensions (Cronbach's alpha of 0.90 for the global score of the questionnaire and Cronbach's α of 0.875 for the first factor and 0.825 for the second) and was cross-culturally adapted following the Canadian version [25]. Regarding the definition of the characteristics of the scale, each item can be scored from 1 to 6, depending on the level of implementation of the scope of practice in each assumption, in relation to the frequency that nurses describe carrying out the activities of their responsibilities. In the case of answering 1, it would refer to this activity being performed "never," while in the case of performing it "always," it would be indicated with 6. The final score of the questionnaire results from the average of each of the questions. Therefore, a score of 3 or less would suggest that the development of the scope of practice is suboptimal. In the best scenario, the maximum score would be 6, and scores above 3 would indicate that nursing activities are being performed more frequently, so the scope of practice is being fully implemented. The two dimensions that constitute the cross-cultural adapted version in Spanish were used, as it was designed for this cultural context of this study.

The independent variables included individual and job characteristics.

Individual characteristics:

- (i) Age (in years).
- (ii) Experience level in the current department (in years).
- (iii) Education level (graduate or postgraduate).
- (iv) Growth need strength: It is a personal characteristic that explains the variability between employees with respect to the need for self-actualization, learning and personal development at work [31]. It was measured with the validated Spanish version of the Job Diagnostic Survey (JDS) using two of its dimensions [26]. Cronbach's alpha obtained acceptable values: 0.91 for the first dimension and 0.72 for the second. It is divided into two dimensions in which both offer different response options in which the individual chooses the characteristics he/she would value when choosing a job. The first dimension evaluates job characteristics that the worker appreciates or would like to have in his job. The second subscale offers two response options to the individual that represent two specific conditions of his job; in it, he has to answer which of the two he would prefer to choose. Both measure those

personal characteristics that allow assessing the need for self-development at work. A higher score on the scales means that the need for development at work is considered to be high.

Work characteristics.

- (i) Autonomy and Psychological Demand: It refers to the ability to choose how to do the job and participate in decisions, and the amount of intellectual demands at work. It was measured using two factors of the Job Content Questionnaire [32], translated and validated in Spanish by Escribà-Agüir et al. [27], one factor to measure the concept of psychological demand at work and another for the concept of autonomy. Cronbach's alpha was rated between 0.74 and 0.88, presenting good reliability.
- (ii) Role Stressors: Role ambiguity, role conflict, and role overload. Role ambiguity and role conflict are defined as the lack of clarity regarding responsibilities and the excess of demands on the worker [33]. On the other side, role overload is defined as a situation in which the demands on the worker are excessive [34]. Role ambiguity and role conflict were measured with the Spanish version Role Ambiguity Scale of Rizzo et al. [35]. The analysis supported the existence of a bi-factorial structure (role ambiguity factor and role conflict factor) that explained 56% of the variance and Cronbach's alpha displayed acceptable value of 0.91. The Spanish version of the National Institute of Occupational Safety and Hygiene [28] was used. For the role overload, we used the Role Overload Questionnaire, developed by Beehr et al. [36] using the Spanish adaptation of Acosta [29]. The internal consistency reliability for role overload was alpha >0.95 for all facets, demonstrating a high correlation of the items.
- (iii) Practice environment: It is defined by Lake et al. [15] as factors that allow nurses to practice to the full scope of clinical practice and deliver safe, quality care to patients. The Practice Environment Scale-Nursing Work Index (PES-NWI), which has been adapted to Spanish by Orts-Cortés et al. [30], was used. The questionnaire showed acceptable internal consistency with Cronbach's alpha between 0.71 and 0.84. The tool has been recommended for its good psychometric properties and ability to compare results between studies and across different countries [37]. It was used in one of the most significant studies in nursing management research, RN4CAST [38], and is also included as a screening indicator for hospital staffing effectiveness in the Joint Commission accreditation standards [39].
- (iv) Nurse-to-patient ratio: Described as the minimum number of nurses in charge of a specified number of patients. The variable was assessed with a single item asking about the number of patients assigned to them on the last shift [40].

- (v) Unit characteristics: Medical, medical-surgical, surgical, and belonging to ICU or not.

2.5. Data Collection. An online questionnaire was developed and conducted through the web platform SurveyMonkey®. Participants were recruited via e-mail with the help of nursing managers of each unit, who were responsible for sending the invitation to participate through the corporation mail address in order to preserve their privacy.

The message included information about the project, the consent for participating and the link to the online questionnaire. For maximizing the response rate, two personalized reminder e-mails were sent and the participation was incentivized with a lanyard as a gift, distributed anonymously after questionnaires returned by each unit nurses' managers [41].

The final survey, with 120 items, included 7 measuring instruments: five to measure job characteristics, one to measure individual characteristics, the demographic data questionnaire and the ASCOP questionnaire to measure the principal variable.

2.6. Data Analysis. Data synthesis and analyses were performed using R version 4.2.2. software. The sample was described using numbers and frequency for categorical variables and mean, standard deviation, minimum, and maximum for continuous variables. Before starting the multilevel analysis, the assumptions of normality of the distribution were examined. The assumptions on which multiple linear and logistic regression analyses are based were checked.

This study focuses on estimating the nursing scope of practice related to nurse's individual and work characteristics. LME [42] was used to determine the significance of the nurse's characteristics in relation to their scope of practice and to estimate the additional effect of the unit, ICU or not ICU. LME, or also called multilevel models or hierarchical models, are extensions of linear regression models that include random effects and correlated errors.

This statistical approach of hierarchical models with random effects assumes that subjects within the same unit type have internal consistency and a hierarchical structure, where individual nurses are nested within hospitalization units or ICU. In our model, the individual and work characteristics were included as fixed effects and a random intercept per nurse was included in the models to adjust for clustering of measurements within belonging or not to ICU.

The percentage of variance in care time explained by the mixed models (R^2) was estimated using the method described by LaHuis et al. [43]. We used R software version 4.3.1. [44] with the lme4 [45] package to perform linear mixed analysis. The level of significance was set as 0.05.

2.7. Ethical Considerations. One-time anonymous survey was performed. The objectives of the study were explained and participants gave free consent to their participation. The study obtained the approval from the Ethics Committee of the (blinded for review) Public University of Navarre (PI: 005/19).

3. Results

We obtained 310 questionnaires and selected the first 270 questionnaires completed entirely to the end by nurses working on hospitalization and ICU. The data imputation process was dismissed considering the potential impact on the analysis due to the substantial amount of missing data in each incomplete questionnaire (more than 90% of the items) and for avoiding significant biases. Furthermore, the literature suggests that the benefits of using imputation in cases of mixed-model analysis are not necessary [46]. The response rate was 67.16%, and although there is no consensus on the appropriate response rate [47] (Morton, 2012), mixed-model designs with higher response rates benefit more than larger sample sizes [48]. However, a recent meta-analysis found that a response rate of 67% is recommended for health sciences studies [49].

3.1. Description of the Variables. Following the conceptual framework of the study, we present the description of the variables. Concerning to the participants' individual characteristics, the nurses had an average age of 39.9 years ($SD = 9.3$), and the mean of years of nursing experience was 11.6 years ($SD = 8.6$). 18.75% ($n = 58$) of our sample had completed the basic nursing degree with any postgraduate degree, but 81.3% ($n = 252$) had only the nursing degree. About the last individual independent variable, measured by the growth need strength questionnaire, the mean of "would like" variable was 8.77 ($SD 1.01$) and the mean of "job choice" section 2.58 ($SD 0.36$). About the characteristics of each unit, 34.8% ($n = 94$) of the nurses worked on an intensive care unit, while 65.2% ($n = 176$) were assigned to hospital units. Otherwise, 23.3% ($n = 63$) worked at a medical unit, 18.9% ($n = 51$) at a surgical unit, and 57.8% ($n = 156$) in mixed medical-surgical unit. A total of 19 different hospitalization units constituted our sample. The first work characteristic, autonomy was 2.80 ($SD 0.30$), psychological demand obtained a mean of 3.05 ($SD 0.290$), role conflict and ambiguity averages were 2.76 ($SD 0.93$) and 3.50 ($SD 1.28$), and the mean for role overload was 3.15 ($SD 1.18$). The mean of nurse-to-patient ratio was 6.72 ($SD = 3.9$), and finally, the mean for the practice environment was 2.76 ($SD 0.39$). Higher scores were related to higher levels of each variable. Regarding the total mean scores of our principal variable, the scope of nursing practice obtained a mean average of 4.05 ($SD 0.72$) (Table 2).

3.2. Linear Mixed Effects Models. Random ICU effect was included. Belonging to the ICU decreased the scope of practice of nurses in 0.15. Aleatory effects of analyzed unit are shown in Figure 2.

The results of the LME analyses conducted with the confounding variables and with adjustment for the corresponding values. As shown in Table 3, the estimated random effects for nursing scope of practice were 0.605 for between-units variance.

TABLE 2: Descriptive statistics.

		Scale	Mean	SD	Observed range	
					Min	Max
Scope of nursing practice	Global score	1–6	4.05	0.72	2.19	5.88
	First dimension	1–6	4.41	0.83	2.20	6.00
	Second dimension	1–6	3.60	0.79	1.70	5.80
Individual characteristics	Age (years)		39.9	9.3	23	59
	Experience level		11.6	8.6	1	35
	Education	81.3%	$n = 252$	—	18.7%	$n = 58$
	Graduate/postgraduate					
	Growth need strength					
	“Would like” “Job choice”	4–10 1–5	8.77 2.58	1.01 0.36	5.09 1.58	10.00 3.67
Work characteristics	Autonomy	1–4	2.80	0.30	1.67	2.67
	Psychological demand	1–4	3.05	0.290	2.33	3.78
	Role ambiguity	1–7	2.76	0.93	1.00	7.00
	Role conflict	1–7	3.50	1.28	1.00	7.00
	Role overload	1–5	3.15	1.18	1.00	5.00
	Nurse to patient ratio		6.72	3.9	1.00	20.0
	Practice environment	1–4	2.76	0.39	1.72	3.66
	ICU/hospitalization	34.8%	$(n = 94)$	—	65.2%	$(n = 176)$

FIGURE 2: Estimated aleatory effects by ICU.

TABLE 3: Linear mixed effects models analysis, including random unit effect.

Parameter	Estimate	95% confidence level		p value
		Lower bound	Upper bound	
Scope of practice				
Intercept	0.605	-0.540	1.749	0.300
Psychological demand	0.561	0.284	0.838	<0.001
Practice environment	0.414	0.202	0.625	<0.001
Role ambiguity	-0.121	-0.207	0.035	0.005
Growth need strength	0.099	0.023	0.1761	0.010

We found a statistically significant effect of psychological demand (0.561, $p < 0.001$), practice environment (0.414, $p < 0.001$), role ambiguity (-0.121, $p = 0.005$), and growth need strength (0.099, $p = 0.010$) on scope of nursing practice. The models explained 24% of the variability within nurses' scope of practice (R_1^2 approx. 0.24). Fixed effects are presented in Figure 3.

All the variables were positively related with the nursing scope of practice except from role ambiguity, that demonstrated a negative trend, so that nurses who showed greater punctuation on those variables were related to a lower scope of practice (-0.12).

Otherwise, nurses with practice environment that multiplied the probability of having upper scope of practice by 0.41, and it occurred the same with the growth need strength that also predicted (0.10 times) the nursing scope of practice. Curiously, nurses with more role psychological demand had 0.56 times higher probability of developing their full scope of practice.

4. Discussion

This study examined the association of the individual and job characteristics on nursing scope of practice on hospital units. First, in this study, the scope of nursing practice (E-ASCOP 4.05) showed higher values than the original study (ASCOP 3.47) [24]. This difference may be explained, on the one hand, by the nature of unit in which the studies were carried out. The Canadian research was conducted in pediatric units, while in our case, we focused on hospital units. Country-specific differences in employment, the legislation and regulation of nursing practice and the level of training of nurses may be another key reason for these variations in scores. The result in our setting, scoring 4.05, shows that the frequency with which nurses performs tasks within their scope of practice is adequate but not optimal, still far from reaching the maximum ASCOP score of 6.

In the study of the nature of the scope of nursing practice, it is important to consider that while nurse work according to a framework of competencies set out in the ASCOP questionnaire, each hospital unit has its own particularities. Therefore, the activities carried out by nurses may differ between different inpatient units, including the ICU, as well as the working environment are conditioned

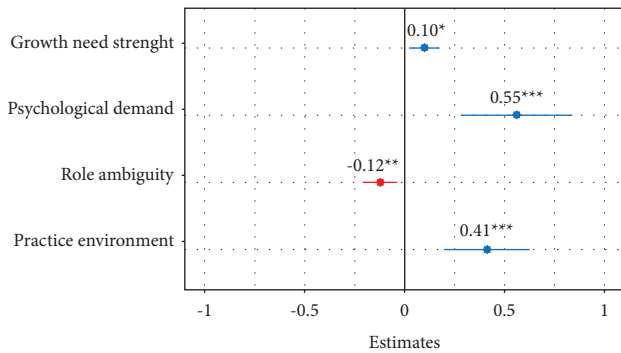

FIGURE 3: Fixed effects of LME. Significance levels are specified with *, **, and ***.

not only by job-related variables but also by the work colleagues themselves. This is why we chose this methodological approach, which considers the effect that belonging to the same unit may have. We consider that nurses working in the same unit will have similar characteristics. In this line, our results show that belonging to ICU decreases nurses scope of practice in 0.15.

Following the model generated in this study, the variables of psychological demand (0.56), practice environment (0.41), role ambiguity (−0.12), and growth need strength (0.10) were the most important characteristics in predicting the scope of nursing practice. The first of these variables is psychological demand, and as in the original study, each increase in this variable has a positive effect on the scope of practice. According to other authors, psychological demands at work are one of the main stress factors perceived by workers, but it has also been demonstrated that this stress can be attenuated by an enhancement of decision-making and a correct definition of specific functions [50]. Contrary to what might be expected, nurses with higher psychological demand are the ones who implement their scope of practice the most. Nurses with higher psychological demand often possess a strong intrinsic motivation and drive to excel in their profession. They are more likely to seek out opportunities for learning, skill enhancement, and career advancement. This motivation pushes them to actively pursue professional development and expand their scope of practice [51].

A second variable determined as a strong predictor of scope of practice in our study is the practice environment, showing a negative effect on the activities carried out by nurses. There are also studies that associate a poor work environment with missed care and negative patient outcomes [15]. It is also known that most of those nursing activities that are omitted are related to comfort activities and communication with patients [52]. Similar results were found in a Turkish research, demonstrating how the practice environment is related to work performance levels and how the staffing has a direct influence on the nurses' scope of practice [53]. It is worth to mention that practice environment, one of the two new variables included in our framework, was found to be a predictor of the scope of nursing practice, as supported by studies such as Pearson's [54] which analyzed the relationship between healthy practice environments and better patient outcomes.

With the addition of the nurse's practice environment as a job characteristic, we intend to develop a predictive model describing the relationship between that variable and the nursing scope of practice. The introduction of that variable was intended to include the more contextual and environmental factors or aspects of the job characteristics, not considered before this study. Understanding the relationship between the practice environment and nurses' scope of practice is essential for optimizing patient outcomes, enhancing job satisfaction, and ensuring the delivery of safe and efficient care [55].

In addition, the obtained results suggest that role ambiguity has a negative relationship with nurses' scope of practice. Tarrant [56] explained that the principal cause of role ambiguity is the inadequate definition of the role, and it has several impacts on job performance. It could be outlined in the following explanation: as a nurse's role is broader, she/he is responsible for more extensive competencies and consequently presents greater performance of the scope of practice. Ambiguity in job roles can hinder nurses' ability to effectively perform their scope of practice. When nurses are uncertain about their authority, decision-making capacity, or the scope/boundaries of their role, they might be hesitant to assume certain responsibilities or may not fully utilize their knowledge and skills. This can limit the extent to which nurses can contribute to patient care and highlight a weakness of nurse's workforce management [57].

Finally, our findings confirm that, among the individual characteristics analyzed, the growth need strength or need of personal self-fulfillment is related to the scope of nursing practice, in contrast to what was published by Fuertes et al. [26]. The intensity of growth need strength reflects the motivation of workers to perform their jobs and their capacity to adapt to change. In our case, the "would like" subscale obtained higher scores (between 71 and 100%), while the "job choice" subscale scored low, indicating that attention should be paid to the nurses' work system. Nurses with high growth need strength seek opportunities for learning, skill enhancement, and career advancement. When nurses' growth needs are met, they are more likely to actively seek out and embrace opportunities to expand their scope of practice. Conversely, if growth needs are not addressed, nurses may become disengaged and less motivated to pursue professional development, leading to a narrower scope of practice [58].

Our model explained 24% of the variance of nurses' scope of practice, compared to 32.5% of the ASCOP model developed by Déry et al. [8]. The Spanish ASCOP model demonstrated the significant influence of four variables on the scope of nursing practice: one variable concerning the individual characteristics of the nurses (growth need strength) and three of the variables referring to job characteristics (role ambiguity, psychological demand, practice environment). In our case, work characteristics were the most sensitive predictors of nursing scope of practice, in contrast to an Australian research [59] which used the Scope-q questionnaire and demonstrated the influence of demographic characteristics rather than work characteristics.

As a main difference compared to the previous model and considering the statistical analysis carried out in the Spanish context, our results do not include the educational level, autonomy, and role overload as predictors of nurses' scope of practice, in contrast with Déry's original study [8], where these variables were three of the five variables included in the model. This could be due to cultural differences, differences in the working conditions of Spanish nurses, and therefore, in their scope of practice.

To optimize nurses' scope of practice, healthcare organizations and leaders must consider these factors. Creating a practice environment that minimizes psychological demand, reduces role ambiguity, and promotes growth need fulfilment is essential. Strategies may include providing adequate support systems, clear role expectations, opportunities for professional development, and fostering a culture of collaboration and shared decision-making. In addition, addressing workload issues, promoting work-life balance, and implementing policies that support nurses' well-being can contribute to a positive practice environment that enhances nurses' scope of practice.

Using mixed effects models within nursing intensive care units, researchers may gain insights into the complex interplay between individual nurse characteristics, unit-level factors, and outcomes. This knowledge can inform evidence-based practices, healthcare policies, and strategies for improving nursing care within healthcare settings. Future research should continue to explore these dynamics to further inform interventions and practices that enhance nurses' scope of practice and consider job-specific differences.

The random effect of UCI is justified for multiple reasons. First of all, such specific care units may show different behaviors and contrary to what might appear, the scope of practice performed by their nurses is lower than in inpatient units. This may be due to technological advances and increasing care needs in recent years, the specific competencies of ICU nurses have been increasing [60]. This acquisition of new responsibilities may have compromised the work beyond their scope of practice and focused ICU nurses on more job-specific tasks, such as the care of specific devices and complex equipment. Secondly, it is well known that nurses working in ICUs are subjected to higher levels of stress. There are even studies that state that these nurses experience a change in their temperament after started working in ICU [61]. These data could lead us to think that belonging to this type of unit has effects not only on the characteristics of the job itself but also on the more personal attributes of these workers.

4.1. Limitations of the Study. One of the main limitations of this study was the elevated number of items (120) that the nurses had to answer. Despite being an easy to understand questionnaire, the response time was approximately 20 minutes, so there were several participants who started the questionnaire but did not complete it.

On the other hand, in our context, no significant differences were found, probably due to the low variability among nurses in their educational level, since in Spain, most nurses hold similar educational degrees (a three or four-year university degree). A line for future research could focus on comparing the scope of practice of nursing managers and general nurses, in which these differences could be studied, because more specialized educational qualifications have begun to be required for these roles.

Moreover, this is the first research in Spain to measure the scope of practice and its determinants. For future projects, a multicenter study could be considered to compare the different regions of Spain, assessing how the policies of each healthcare regional service affect both nurses' working conditions and the scope of their practice. In addition, it would be valuable to explore the particularity of the ICU, potentially needing a distinct study approach.

5. Conclusions

In this study, we have determined that there are individual and job characteristics that predict the scope of nursing practice in hospital units. Mixed effects models allow researchers to better understand the relationships between individual nurses and hospital units, providing valuable insights for nursing practice, healthcare management, and policy decisions. This new statistical approach complements the original analysis by including the random effect of belonging to a particular unit (ICU or medical-surgical unit) on nurses' scope of practice, which has not been previously considered. Nurses belonging to same unit had similarities and the results are different between those groups.

The scope of practice of Spanish hospitalization nurses demonstrated a broader range of practice than that of Canadian nurses. In the model we present, the influence of psychological demand, practice environment, role ambiguity, and growth need strength were the predictive variables of the nursing scope of practice.

Although the results showed better levels of scope of nursing practice than in the original study, it remains suboptimal. With the identification of the factors that are determinants, we can propose strategies to improve them and thus facilitate nurses to implement more broadly their scope of practice.

Data Availability

The mixed effects models data used to support the findings of this study are available from the corresponding author upon request.

Ethical Approval

This study has been approved by the Ethics Committee of the Public University of Navarre (PI: 005/19).

Consent

Written informed consent was obtained from the participants.

Conflicts of Interest

The authors declare that they have no conflicts of interest.

Authors' Contributions

The authors contributed equally to this study.

Acknowledgments

This work was supported by the Spanish Association of Deans of Nursing Faculties (CNDE). The authors would like to thank all nurses who participated in this study.

Aim: This study aims to investigate the influence of medical explainable artificial intelligence (XAI) on the innovation behaviour of nurses, as well as explore the dual-pathway mediating effect of AI self-efficacy and AI anxiety and organizational ethical climate as the moderating effect.

Background: To address the practical application of medical AI technology, alleviate the scarcity of medical resources and fulfil the medical and health demands of the public, it is crucial to improve the innovation behaviour of nurses through the use of medical XAI.

Methods: A cross-sectional survey was conducted involving 368 Chinese nurses working at tertiary and secondary hospitals in Anhui Province, Jiangsu Province, Zhejiang Province and Shanghai.

Results: Implementing medical XAI significantly enhanced the innovation behaviour of nurses. Anxiety and self-efficacy regarding AI mediated the connection between medical XAI and the innovation behaviour of nurses. Furthermore, the organizational ethical climate positively moderated the relationship between medical XAI and AI self-efficacy.

Conclusion: Medical XAI helps to enhance nurses' AI self-efficacy and reduce AI anxiety, thereby enhancing nurses' innovation behaviour. An organizational ethical climate enhances the positive relationship between medical XAI and AI self-efficacy.

Implications for Nursing Management: Organizations and technology developers must augment the study about XAI and the system design of human-centred AI technology. The organizations aim to enhance the education and training of nurses in AI, specifically focussing on boosting nurses' self-efficacy in utilizing AI technology. Moreover, they want to alleviate nurses' fear of new technological advancements. Hospital administrators and leaders develop strategies to address the ethical atmosphere inside their organization.

Keywords: AI anxiety; AI self-efficacy; medical explainable artificial intelligence; nurses' innovation behaviour; organizational ethical climate

1. Introduction

Following numerous upgrades and reforms within China's medical sector, it is evident that the overall standard of healthcare has experienced notable enhancements [1, 2]. However, due to the imbalance in the supply and demand of nursing services, as well as the unreasonable allocation of medical resources, it becomes increasingly evident that the

current traditional nursing service system could not meet the nursing needs in China [3–6]. The emergence and development of medical artificial intelligence (AI) has led to breakthroughs in exploring new models of medical service [7, 8]. In China, ophthalmology and dentistry are the two departments with a high prevalence of medical AI technology [9, 10]. For example, the first AI eye centre for cataracts has been established in Guangzhou, China [11]. AI

is widely used in ophthalmology to assist in the diagnosis and therapeutic monitoring of ocular diseases such as diabetic retinopathy [12, 13], ocular tumours [14] and glaucoma [15]. AI is also widely used in dentistry to diagnose dental diseases such as caries and periapical inflammation [16, 17], formulate personalized treatment plans [18] and introduce dental implant robot [19], which improves the disadvantages of traditional oral diagnosis and treatment [20]. Nurses, as potential users of AI technology, are in a key position to shape and lead the development of modern AI in medical [21–23]. Nurses' innovation behaviour is beneficial to the popularization and application of medical AI technology, which could also drive the transformation and innovation of the nursing service in China [7, 8].

The concept of nurses' innovation behaviour pertains to the exploration and creation of novel technologies or methodologies to enhance health promotion, disease prevention and the quality of care [24, 25]. Labrague et al. [26] proposed the view that trainee nurses are willing to embrace technological advances and engage in innovation behaviour in nursing practice. To maximize the efficiency of medical AI in nursing, nurses contemplate methods to enhance or modify the implementation of medical AI in clinical and nursing practice [27, 28]. The barrier to nurses' involvement in AI research and collaborative design is a communication gap between nurses and technologists [29]. In addition, scholars have proposed that explainable artificial intelligence (XAI) should be conducted in light of the black-box nature to better understand the decision-making process of AI technology [30, 31]. The black-box property of AI technology refers to the fact that their decision-making processes and reasons are difficult to understand and explain [32]. Nurses must possess sufficient expertise in utilizing AI devices and effectively applying their knowledge in practice; however, an in-depth comprehension of the intricacies underlying the technology may not be a prerequisite [27, 33]. Thus, the explanation of AI should be modelled based on philosophy, psychology and the cognitive science of human interpretation [34] and cannot be explained solely through a technical perspective [35].

Arrieta et al. [36] proposed the concept of XAI from an audience perspective, which aims to make the decision-making and prediction processes within AI systems transparent and understandable. In the medical field, XAI has been defined as the extent to which nurses are able to understand the reasons for decisions made by AI systems [37, 38]. Furthermore, including medical personnel in developing and ultimately implementing healthcare AI technology can enhance their expertise rather than technology replacing them. This collaborative approach fosters a trustworthy relationship between medical professionals and technology, facilitating the advancement and widespread adoption of healthcare AI technology [27]. Researchers proposed to explore the XAI from the user's perspective in the technology development process to the application [30, 36, 39]. A limited number of studies exist investigating the potential impact of XAI on nurses' innovation behaviour [40].

According to the job demand–control model [41], medical AI technology changes nurses' work characteristics. It impacts their job requirements and control, affecting their psychological characteristics. Nurses with high self-efficacy have strong confidence and believe they can better cope with high job requirements, promoting innovation behaviour [8]. AI self-efficacy is defined as an individual's perception of their ability to use computers, rather than an individual's knowledge and understanding of computers [42, 43]. However, nurses with lower job control, to a large extent, have higher levels of stress and skill anxiety when their organizations implement new technology, refusing to use new technologies and avoid innovation behaviour. AI anxiety refers to the fear and anxiety that AI technology creates in individuals when it is beyond their control [7]. Social cognitive theory suggests that the environment influences individual cognition and behaviour [44]. The ethical climate of an organization is comprised of the collective knowledge and understanding of its members regarding what constitutes ethical conduct and how to resolve ethical dilemmas or problems [45], inevitably influencing the proactive behaviour and cognition of nurses [46–48].

This study explored the relationship between medical XAI and nurses' innovation behaviour, examining how AI self-efficacy and AI anxiety mediate this relationship. Additionally, the study investigated the moderating role of organizational ethical climate. By addressing these aspects, this research revealed how enhancing medical XAI can promote nurses' innovation behaviour, further advancing the integration of medical AI technology into nursing practice. It provided new insights for innovation in nursing management.

2. Research Hypothesis

2.1. XAI and Nurses' Innovation Behaviour. The present evaluation of medical XAI primarily evaluates the explainability of the model and application effect. The explainability takes accuracy, causality and stability as the measurement indicators, while the application takes the users' security, fairness and visualization as the evaluation indicators [49]. The essence of medical XAI is the interpretation of AI models developed from large amounts of intricate medical data [50] to make people understand how AI systems arrive at particular conclusions, recommendations and algorithms they rely on. Research has indicated that FATE (fairness, accountability, transparency and explainability) has a positive effect on the acceptance of algorithmic services, providing practical suggestions for the development of human-centred or responsible and trustworthy AI [51–53]. To measure XAI, the present study primarily adopts Shins' perspectives.

Nurses are likely to pay more attention to XAI, an important factor influencing the development and implementation of medical AI [28, 35, 54]. Social cognitive theory proposes that goals can elicit and direct motivational outcomes [55, 56]. Medical AI is highly explainable and can explain the foundation of its decisions, resulting in nurses' safety, responsibility and transparency, which improves

nurses' trust in medical AI technology [30, 57]. With improving the cognition and trust in medical AI technology, nurses may be willing to adopt and utilize medical AI technology in order to better achieve their goals and, to some extent, inspire innovation behaviour [26]. As an applied discipline, nursing actively promotes pursuing and delivering innovative medical services and emphasizes innovation as an opportunity to generate progress [58]. A lack of explainability in medical AI or algorithms hinders nurses' understanding and acceptance, diminishing their trust in such systems [54, 59]. Nurses adopt traditional diagnosis and treatment modes, avoid taking risks and do not actively innovate and explore new medical service methods.

Hypothesis 1. Medical XAI positively affects nurses' innovation behaviour.

2.2. Mediating Role of AI Self-Efficacy Between Medical XAI and Nurses' Innovation Behaviour. AI self-efficacy refers to an individual's belief in using AI technology to achieve work goals [60]. A high sense of self-efficacy implies that individuals can perform various tasks and job requirements effectively. Individual confidence leads to better performance and effectiveness of the AI technology, motivating the user to approach job challenges with greater initiative. According to the job demand-control model, the introduction of medical AI technology increases the job demands on nurses, which represent stressors in the work environment such as time pressure and excessive workload [61, 62]. Job control refers to an individual's ability to control work and tasks [63]. Job demand-control theory puts forward the buffering hypothesis that improving the sense of job control can reduce the negative impact of high job demands [64]. When medical XAI improves, it helps nurses' control and use medical AI to mitigate the negative effects of high work demands. Therefore, when nurses' sense of control over medical AI is enhanced, it helps to improve nurses' sense of AI self-efficacy. A high level of medical XAI inspires nurses to believe that AI can assist in the making of accurate and valuable auxiliary decisions, helps them gain confidence in AI technology for medical AI diagnosis and treatment and strengthens their trust in AI, which in turn improves their comprehension of novel technologies and knowledge, their conviction in task completion and their self-assurance.

Moreover, nurses with high self-efficacy are confident in their ability to solve challenges and foster innovation using AI technology [7, 8]. They are open to experimenting with novel approaches and technologies to deliver superior medical services and treatment to patients. Furthermore, nurses with high self-efficacy are eager to engage in continuous learning and technological innovation and seek opportunities to solve clinical practical problems such as diagnosis, treatment and AI technology improvement [65]. Therefore, medical XAI helps to improve the self-efficacy of nurses and ultimately promote their innovation.

Hypothesis 2. AI self-efficacy plays a mediating role between medical XAI and nurses' innovation behaviour.

2.3. Mediating Role of AI Anxiety Between Medical XAI and Nurses' Innovation Behaviour. AI anxiety refers to an individual's irrational anxiety and emotional response, leading to behaviour such as avoidance of use and reflecting their fear and unease about AI beyond their control [66]. According to the addictive strain hypothesis proposed in the job demand-control model, employees working in high job demand, low job control environments have the most negative mental health and the highest stress levels [61, 67]. Although AI technology is rapidly being used in the medical field for its high accuracy, high efficiency and noncontact treatment, for nurses who lack knowledge and understanding of AI technology, the introduction of medical AI technology can lead to a rise in nurses' job demand and a decrease in job control. Nurses' job stress arises from the imbalance between job demand and job control [8]. Individuals in long-term high pressure will cause anxiety and other bad health state [68]. Research showed that more information and knowledge about AI technology can help users reduce their anxiety when facing new technologies [35, 69]. Certain concerns can be alleviated by engaging in transparent discussions about the ethics of AI in healthcare [70]. Medical XAI has the potential to aid nurses in understanding the underlying logic behind judgements made by AI algorithm models, partially reducing their anxiety associated with AI.

The limited comprehension of AI technology among nurses will impact their concern regarding their skill and expertise in medical AI [71], thus affecting their motivation to participate in innovation and their level of innovation ability. Furthermore, AI anxiety also includes concerns about technology reliability, privacy and security. A lack of motivation and enthusiasm for innovation behaviour, scepticism and resistance to technological change and a reluctance to attempt new AI technology solutions or alter established work processes may result from numerous technical anxieties among nurses [72]. If nurses can overcome AI anxiety and actively respond to new work requirements, they can adapt and accept AI technology and believe that these technologies can provide better medical care. The promotion and widespread adoption of technology among nurses is contingent upon user-friendliness [73]. These technologies can relieve nurses of tedious tasks, freeing them to devote more time and energy to core nursing work and tasks that promote nursing innovation [35].

Hypothesis 3. AI anxiety plays a mediating role between medical XAI and nurses' innovation behaviour

2.4. The Moderating Role of Organizational Ethical Climate. Organizational ethical climate pertains to the collective knowledge and understanding of its members regarding moral dilemmas and influences individuals' attitudes, beliefs

and intentions towards moral issues. Furthermore, it profoundly impacts the ethical conduct and decision-making of the entire organization [74]. According to the social cognitive theory, individual activities are formed by interacting with three factors: individual cognitive characteristics, external environment and individual behaviour. Individuals will constantly regulate themselves by comparing their own behaviours with those advocated by the organizational ethical climate [55, 75]. The positive organizational ethical climate emphasizes the ability of nurses to provide a high level of medical care, as well as the ethical norms and professional principles that nurses should follow when making decisions [76–78]. An effective organizational ethical climate can give nurses access to resources and information by establishing medical XAI with principles of transparency, accountability, safety and fairness [52]. Adoption of medical AI helps nurses to provide a higher level of health care to their patients [79]. Therefore, in a positive organizational ethical climate, organizations prioritize the development of applications related to medical AI. Nurses are willing to continue to learn professional knowledge of AI technology to improve their awareness, application and innovation ability of medical AI [35, 80]. These nurses are optimistic about their ability to effectively implement medical AI technology to deliver successful diagnosis and treatment services. Consequently, a strong ethical climate within an organization enhances the positive correlation between medical XAI and nurses' AI self-efficacy.

Hypothesis 4. Organizational ethical climate has a moderating effect on medical XAI and AI self-efficacy.

Conversely, medical personnel may develop confidence in and endorse the management and organization due to a robust ethical climate within the institution [39, 46]. Nurses find it more manageable to comprehend the decisions and outcomes of medical AI when they have access to detailed information and relevant explanations about medical AI [72]. Social cognitive theory emphasizes the individual's observation of the environment and imitation [44]. Nurses observe colleagues beforehand when they are sceptical about their ability to use medical AI. Observing the colleague successfully use a medical AI to perform a job task can reduce the observer's anxiety [81]. In an organizational ethical climate, information transfer and communication mechanisms ensure that nurses understand the explainability of healthcare AI systems and reduce their AI anxiety by eliminating the sense of uncertainty surrounding their decisions. The strong organizational ethical climate weakens the negative relationship between medical XAI and AI anxiety. Theoretical model of this study is presented in Figure 1.

Hypothesis 5. Organizational ethical climate has a moderating effect on medical XAI and AI anxiety.

FIGURE 1: The hypothesized study model.

3. Research Methods

3.1. Sample and Procedure. This study focused on two departments (ophthalmology and dentistry), the frontier fields of AI technology application in China's medical field. Due to the convenience and variety of image data acquisition in these departments, they were transformed into research departments, with nurses serving as subjects of the investigations. This study was conducted from May 2023 to July 2023, with nurses from private hospitals and the top three hospitals in Anhui Province, Jiangsu Province, Zhejiang Province and Shanghai. The requirements of the respondents in this study were junior professional titles, intermediate professional titles and licenced assistant physician titles. They are working on healthcare related to medical AI and have worked in the department for at least 6 months.

Common method bias (CMB) refers to the perceived covariation between predictor variables and calibration variables due to the same data sources or the same raters, the same measurement environment, the context of the research and the characteristics of the items [82]. To prevent the effects of CMB, this study conducted a two-stage investigation [82], with a 2-month interval between the two surveys. The first stage of the survey began in May 2023. The respondents who completed the survey left the last four digits of their mobile phone numbers as matching codes. The distribution of 550 questionnaires resulted in the retention of 523 valid questionnaires after excluding incomplete and invalid questionnaires. In July 2023, questionnaires were disseminated to respondents who had completed the initial phase of the investigation. After eliminating unqualified and incomplete responses, the two questionnaires were compared. The recovery rate for the 368 valid questionnaires that were gathered was 66.91%.

3.2. Measurements. The questionnaire used in this study consists of three parts. The first part explains that the questionnaire was used for academic research only and that the participants in the study participated voluntarily and anonymously, with an undertaking to keep the questionnaire data safe and to safeguard the privacy of the participants. The second part deals with the demographic characteristics of the participants (age, gender, education and clinical experience). The third section deals with the

measurement of five variables, including medical XAI, AI self-efficacy, AI anxiety, organizational ethical climate and innovation behaviour. The variables were measured using reliable and mature scales developed. Likert's five-point scale was used, with one to five ranging from 'Strongly Disagree' to 'Strongly Agree'. For the initial scales that were in English, in order to minimize the impact of cultural and linguistic differences, a translation-back-translation method was used to convert the relevant scales into Chinese. In addition, the questionnaire items were appropriately adjusted according to the study context. Before formally distributing the questionnaires, three nurse leaders were asked to review the questionnaires to ensure that the internal logic of the questionnaires was smooth and the use of terminology was correct.

Medical XAI was adopted from the scale of explainable AI by Shin [51], including four items. The representative item was 'I found medical AI are easily understandable'. The scale's reliability coefficient was 0.73.

AI self-efficacy was adopted from the scale of robot use self-efficacy in healthcare work by Turja et al. [83], including six items. The representative item was 'I'm confident in my ability to learn how to use medical AI if they were to become part of my unit'. The scale's reliability coefficient was 0.84.

AI anxiety was measured from Huo et al. [7] four items. The representative item was 'With the large scale of medical AI application, I am concerned that medical staff lose control in the process of medical services'. The scale's reliability coefficient was 0.75.

Innovation behaviour was measured from Bao et al. [24] 10 items. The representative items were 'When working with medical AI, I will find the problems and be willing to solve them'. The reliability coefficient of the scale was 0.94.

Organizational ethical climate was measured from Vidaver-Cohen [84] five items. The representative item was 'The hospital where I work will require medical personnel to adhere strictly to relevant ethical guidelines when introducing new technologies such as medical artificial intelligence'. In this study, the scale's reliability coefficient was 0.87.

3.3. Ethical Consideration. In the survey, an informed consent letter was sent to participants, explicitly stating that their involvement in the study was both voluntary and anonymous. After completing the survey, the collected data were securely stored to ensure the confidentiality of the participants. Our research complied with ethical norms and laws. The Science and Technology Research Ethics Committee of Anhui University of Science and Technology approved the protocol of this study (Ethical ID: LW-2023-001).

3.4. Data Analysis. The data analysis was conducted using Amos 26.0 and SPSS 26.0. First, this study used the Harman one-way test by SPSS 26.0 to prevent CMB may cause serious confusion in the research results and potentially misleading the conclusions [82]. All items of the variables were subjected to unrotated factor analysis. If the first principal component explained less than 40% of the variance was obtained, it means that there is no significant CMB.

Second, the reliability and validity tests are an important condition to ensure the accuracy of the results of data analysis. Before hypothesis testing, this study needs to evaluate the reliability and validity of variable items. The reliability denotes the degree of internal consistency and stability of the measurement instrument, which is used to examine the reliability of variable measurements. The validity refers to the degree to which a test indicator can accurately measure the variable to be measured, that is, the accuracy of measurement results. It reveals the relationship between variables and measurement items.

Among them, the reliability test is usually evaluated by Cronbach's α coefficient. When Cronbach's α coefficient is higher than 0.7, the model has high internal consistency [85, 86]. Confirmatory factor analysis (CFA) is a common method to test the discriminative validity. In addition, in order to compare actual data and model fit to meet validation statistical criteria, enhancing the explanatory power and reliability of the assessment model, CFA methods can also be tested [87]. Commonly used validity indicators include $\chi^2/df \leq 3$, RMSEA ≤ 0.08 , CFI ≥ 0.90 , TLI ≥ 0.90 , NFI ≥ 0.90 and IFI ≥ 0.90 [88].

Further, Pearson was used to conduct a correlation analysis of the variables to test whether there is a multicollinearity problem between the variables in this study. When the correlation coefficient between variables exceeds 0.75, it is considered that the correlation between variables is high and there may be a multicollinearity problem [89, 90]. However, correlation analyses can only indicate whether there is a correlation between the variables and do not reveal the causal relationship between variables and the degree of its impact.

Finally, the hypotheses proposed, including main, mediating and moderating effects, are then tested when the reliability and validity of the measurement model meet the standard, and the data do not have serious CMB and multicollinearity problems.

4. Results

4.1. Demographic Characteristics. Table 1 presents the demographic characteristics of nurses, valid sample 368. Among them, the gender was female, accounting for 76.4%; most participants were less than 30 years old (82.6%), 71.7% had a bachelor's degree, 6.5% had a master's degree or above, 45.9% had less than 1 year of clinical experience, and 41.0% had 1–5 years of clinical experience.

4.2. CMB and CFA. Before commencing the investigation, this study implemented anonymity measures, including the hiding of variable names and the linguistic modification of questionnaire items, to minimize the influence of CMB. Nevertheless, it remained imperative to examine the potential bias. By employing Harman's single-factor test, we ascertained that the first common factor accounted for 37.39% of the variance in the total variables. This value is below the threshold of 40%, which signifies no obvious CMB in the research data.

TABLE 1: Nurse's characteristics ($N = 368$).

Variables	Frequency (f)	Percentage (%)
Gender		
Male	87	23.6
Female	281	76.4
Age		
20 or less	85	23.1
21–30	219	59.5
31 to 40	39	10.6
41 to 50	23	6.3
50 or higher	2	0.5
Education level		
High school	54	14.7
Junior college	26	7.1
University	264	71.7
Master and above	24	6.5
Clinical experience		
1 or less	169	45.9
1–5	151	41.0
6–10	39	10.6
11–20	6	1.6
21 or higher	3	0.8

In this study, CFA was used to examine the discriminant validity of the variables. Table 2 shows that the five-factor model had the best fit ($\chi^2/df = 2.548$, NFI = 0.902, IFI = 0.938, TLI = 0.923, CFI = 0.937, RMSEA = 0.065). All indexes were better than those of other models, indicating that the variables in this study had good discriminant validity.

4.3. Correlation Study. Table 3 shows the mean value, standard deviation and correlation among variables in this study. The data shown in Table 3 imply that medical XAI is positively correlated with AI self-efficacy ($r = 0.430$, $p < 0.01$), innovation behaviour ($r = 0.338$, $p < 0.01$) and negatively correlated with AI anxiety ($r = -0.262$, $p < 0.01$). AI self-efficacy was positively correlated with innovation behaviour ($r = 0.409$, $p < 0.01$), whereas AI anxiety was negatively correlated with innovation behaviour ($r = -0.321$, $p < 0.01$). These results provide a foundation for investigating the potential mediating effect of AI self-efficacy and AI anxiety on the relationship between medical XAI and nurses' innovation behaviour.

4.4. Hypothesis Test Results. Figure 2 presents the data after controlling for nurses' age, gender, education and clinical experience. Medical XAI positively impacts nurses' innovation behaviour ($\beta = 0.319$, $p < 0.001$), supporting Hypothesis 1. Furthermore, medical XAI had a positive impact on AI self-efficacy ($\beta = 0.406$, $p < 0.001$), and AI self-efficacy had a positive impact on nurses' innovation behaviour ($\beta = 0.317$, $p < 0.001$). Medical XAI had a negative effect on AI anxiety ($\beta = -0.240$, $p < 0.001$), and AI anxiety had a negative effect on nurses' innovation behaviour ($\beta = -0.154$, $p < 0.001$).

The bootstrap method was adopted to examine the mediating effect of AI self-efficacy and AI anxiety. Table 4 summarizes the results. Mediator Path 1 is medical

XAI \rightarrow AI self-efficacy \rightarrow innovation behaviour, which tested the mediating effect of AI self-efficacy on medical XAI and innovation behaviour. The indirect effect size was 0.093 with a 95% confidence interval [0.042, 0.146], excluding 0. The mediating effect of AI self-efficacy was significant, and Hypothesis 2 was verified. This result confirms that AI self-efficacy plays a significant mediating role in the relationship between medical XAI and innovation behaviour. This means that improving medical XAI can increase nurses' AI self-efficacy and thus promote innovation behaviour among nurses.

Similarly, Mediator Path 2 was medical XAI \rightarrow AI anxiety \rightarrow innovation behaviour, testing the mediating effect of AI anxiety between medical XAI and innovation behaviour. 95% confidence interval [0.003, 0.065], excluding 0, estimated the indirect effect size to be 0.031. The mediating effect of AI anxiety was found to be significant, confirming Hypothesis 3. This result confirms that AI anxiety plays a significant mediating role in the relationship between medical XAI and innovation behaviour. This means that it is possible to reduce nurses' AI anxiety and thus promote their innovation behaviour by improving medical XAI.

As shown in Figure 2, the interaction terms of medical XAI and organizational ethical climate had a significant positive effect on AI self-efficacy ($\beta = 0.088$, $p < 0.05$), assuming that Hypothesis 4 was verified. The interaction term of medical XAI and organizational ethical climate was not significantly related to AI anxiety ($\beta = -0.075$, n.s.), not supporting Hypothesis 5.

In addition, based on the simple slope method recommended by Aiken and West [91], this study conducts the interaction effect diagram of the interaction of medical XAI with organizational ethical climate on AI self-efficacy. Figure 3 shows that the positive effect of medical XAI on AI self-efficacy is higher when the organizational ethical climate is strong.

TABLE 2: Results of confirmatory factor analysis (CFA).

Model	Variables	χ^2/df	NFI	IFI	TLI	CFI	RMSEA
Five-model	XAI, AISE, AIA, IB, OEC	2.548	0.902	0.938	0.923	0.937	0.065

5. Discussion

Based on job demand–control theory and social cognitive theory, this study explores the path mechanisms of medical XAI influencing nurses’ innovation behaviour and draws the following conclusions:

Medical XAI has a significant positive impact on nurses’ innovation behaviour, supporting H1. The application of medical AI technology is mainly divided into auxiliary diagnosis and treatment technology and independent diagnosis and treatment technology [7]. The use of medical AI technology, such as image acquisition and surgical assistance, improves diagnostic efficiency and accuracy, reduces the work pressure of nurses and makes the assistant AI technology updated and popularized [15]. However, for some AI robots to independently complete online diagnosis and answer questions, the explainability of the technical algorithms cannot yet be accepted or recognized, and nursing the actual work needs matching is low. The effect of the application is not very good. The two medical AI technologies have different levels of explainability, with the more explainable medical AI technology being more acceptable and trusted by nurses, so there are differences in technology promotion and innovation development. The result of this study provides an answer to why there is a certain degree of divergence between the innovation and

development of medical AI technology and why medical XAI promotes the innovation behaviour of nurses. That is, nursing managers should pay attention to the fact that medical XAI can influence nurses’ innovation behaviour in nursing practice.

This study suggests that there are two different path mechanisms for the influence of medical XAI on nurse innovation behaviour. Specifically, the first pathway is that AI self-efficacy mediates the relationship between medical XAI and nurse innovation behaviour, supporting H2. Shin [73] proposed that medical XAI would enhance nurses’ trust in AI technology and enhance nurses’ confidence and intrinsic motivation to improve innovation. The core of AI self-efficacy is the belief that individuals can effectively use AI to accomplish their work [92]. Nurses can enhance the practicality of medical AI technology and improve technological innovation by offering developers feedback regarding its safety, accountability, transparency and explainability [36] and promote technological innovation. When medical XAI is at a high level, nurses perceive medical AI as simple and easy to understand, increasing nurses’ confidence in utilizing medical AI and applying medical AI to solve problems in clinical practice. Because nurses believe they can overcome challenges and successfully apply these technologies. Nurses with high AI self-efficacy will hold a more open and inclusive attitude towards medical AI and

TABLE 4: Direct and indirect effects.

Dependent variables	Paths	Effect size	Standard error	95% confidence interval	
				Upper limit	Lower limit
Innovation behaviour	Total effect	0.296	0.046	0.205	0.386
	Direct effects	0.172	0.048	0.077	0.266
	Indirect effects	0.124	0.028	0.071	0.180
	Mediator Path 1: XAI → AI self-efficacy → innovation behaviour	0.093	0.027	0.042	0.146
	Mediator Path 2: XAI → AI anxiety → innovation behaviour	0.031	0.016	0.003	0.065

Abbreviation: XAI, medical explainable artificial intelligence.

FIGURE 3: The moderating effect of organizational ethical climate on the relationship between medical XAI and AI self-efficacy.

are more willing to use the new technology to solve problems in clinical practice [43, 60, 92], thus promoting innovation behaviour.

The second pathway is that AI anxiety mediates the relationship between medical XAI and nurse innovation behaviour, supporting H3. According to the job demand–control model, the four combinations of job demand and job control affect employee creativity [93]. The combination of high job demand and low job control is more likely to lead to higher exhaustion and lower motivation [94]. It is challenging for nurses to identify these errors or biases due to the opacity of AI [95], which does not provide a foundation for overturning or correcting the decision. Low levels of medical XAI can become the job demand for nurses, especially when nurses are required to learn to utilize medical AI for more complex care tasks, putting nurses in a state of anxiety, which is consistent with a state of high job demand and low job control. Whereas anxiety as a poor mental leads to negative behaviour [96], it can reduce nurses' acceptance of medical AI as a new technology and they will be reluctant to engage in innovation behaviour related to medical AI. The results reveal that nurses can enhance their understanding of medical AI technology by learning relevant knowledge in medical XAI. This can increase self-efficacy in using medical AI technology and reduce AI anxiety, which help nurses make informed decisions in nursing practice. On the one hand, it promotes nurses' innovation behaviour, advancing the development and innovation of the nursing services industry. On the other hand, once nurses become proficient in medical AI technology, they can also assist developers in improving technology or algorithms, promoting the emergence of more advanced and user-friendly medical AI technology, thereby advancing nursing innovation and development. Additionally, the results also address the cognitive pathways explaining why medical AI technology has both positive and negative impacts [69, 97, 98].

Finally, the study introduced organizational ethical climate as a moderating variable. Organizational ethical climate positively moderated the relationship between medical XAI and AI self-efficacy, supporting H4. However, the moderating effect was not significant in the relationship between medical XAI and AI anxiety, not supporting H5. This may be because the application and promotion of medical AI technology are still developing, and nurses are not too worried about the technology. Social cognitive theory emphasizes the individual's observation of the environment and imitation [44]. Fairness, accountability and transparency will be emphasized in the positive ethical climate of the organization [99, 100]. This positive environment enhances the importance of medical AI in organizations and makes organizations inclined to introduce medical AI devices or technologies with high explainability. An organizational ethical climate can help nurses develop a correct understanding of medical AI technology, enabling them to rigorously monitor AI in nursing practice. Such behaviour aids in preventing individuals from evading medical responsibilities, enhancing trust in AI and reducing the negative impacts of new technologies. This study indicates that nursing management personnel can introduce the implementation of ethics education and training systems related to AI technology within organizations, leading to a significant improvement in nurses' AI self-efficacy. The organizational ethical climate as a moderating variable can resolve doubts for organizations about how and what to intervene. Establishing a positive organizational ethical climate can not only facilitate the integration of medical AI technology into nursing practice but also promote innovation in the nursing services and improve the patient care experience.

6. Conclusions

This study provides new insights into the factors that promote nurses' innovation behaviour. Overall, this study explored the dual-path model of the impact of medical XAI on nurses' innovation behaviour based on the job demand–control model and social cognitive theory, and this study examined how medical XAI affects nurses' innovation behaviour. It can be concluded that AI self-efficacy and AI anxiety mediated the relationship between medical XAI and nurses' innovation behaviour separately. As a moderating variable, organizational ethical climate moderates the effect of medical XAI on nurses' AI self-efficacy. The findings suggest that the explainability of medical AI in terms of fairness, accountability and transparency can be enhanced from the cross-disciplinary perspective of humanities and social sciences, which can provide new ideas for the development of medical AI technology and system design, and provide theoretical support for promoting and training nurses' innovation behaviour. In addition, strengthening the promotion and application of medical AI technology and enriching new nursing service models can provide new ideas for solving the problems of shortage of medical personnel and unequal distribution of medical resources.

6.1. Implications for Nursing Management. This study explores the relationship between medical XAI and the innovation behaviour of Chinese nurses, with practical implications for the nurse community, organizational managers, student nurse education schools and the field of medical AI. Details are shown as follows:

1. Cross-disciplinary collaboration is carried out to encourage nurses' participation in the medical AI design. There is a need to empower nurses to collaborate with technologists, doctors and other healthcare professionals to jointly develop and evaluate AI solutions. This interdisciplinary collaboration helps ensure the applicability of AI technology devices. For example, it is suggested that organizations and technology developers need to enhance the understanding and research of medical XAI from the perspective of humanities and social sciences for system design of human-centred medical AI technology. In healthcare, medical XAI is critical for nurses, patients and other stakeholders, who must understand how AI technology makes decisions and what data are used to make predictions or diagnoses [39, 73]. Organizations and technology developers need to prioritize the design of user-friendly interfaces that facilitate nurses' understanding of medical AI outcomes and decisions. We ensure that the decision-making process of the AI system is transparent, and establish feedback mechanisms so that nurses can report and discuss issues and challenges in practical use. Furthermore, it is crucial to establish traceability and reviewability mechanisms within the decision-making process of medical AI. This will enable healthcare workers to verify the reliability of the system's decisions and hold it accountable for the results that it produces. Enhancing the legitimacy and acceptability of medical AI technology is crucial for fostering its integration into clinical practice.
2. Enhance nurse education and training. Organizations or societies should provide ongoing education on medical AI technology to enable nurses to understand and utilize these tools, enhance nurses' self-efficacy and reduce nurses' anxiety and concerns about new technology. Training should include how to explain the AI decision-making process and effectively use these technologies in daily nursing practice such as encompassing fundamental information, practical applications, technical principles and operational procedures about medical AI. Training programs effectively enhance nurses' comprehension of the potential and prospects of medical AI [29, 101]. These programs also equip nurses with the necessary skills and knowledge to effectively utilize AI technology [26]. Organizations can utilize practical scenarios to facilitate nurses' understanding and recognition of the practical implications of AI technology and bolster their confidence in and self-assurance regarding using such technology. Nurses can better adapt and utilize

medical AI technology and reduce anxiety with continuous support and guidance from relevant medical organizations.

3. The ethical issues of medical AI should be paid attention to, and a positive organizational ethical climate should be established. The organizations strengthen research on medical AI ethics and set up a special research institute or ethics committee responsible for researching and regulating issues related to medical AI ethics. These institutions may comprise professionals and academics with diverse areas of expertise, including but not limited to medicine, ethics, law and computer science. They engage in interdisciplinary collaboration to incorporate various perspectives and interests, aiming to offer more efficient resolutions for ethical dilemmas in research and response [34, 102]. It is essential to develop a framework and guiding principles for ethical issues in medical AI through research and discussion, which can cover data use, algorithmic fairness, transparency, privacy protection, accountability and other aspects of medical AI technology to guide the development, application and regulation of medical AI technology. The organizations establish contact with international partners to share experiences and research results. Countries and regions may have different concerns and research on the ethical issues of medical AI [98]. By fostering international collaboration, we can advance global cooperation in investigating and resolving ethical concerns associated with medical AI and gain knowledge from one another [103, 104].

6.2. Limitations. The present study has some limitations. First, the study focused on dental and ophthalmology nurses as the research participants and did not specifically address the impact of medical AI implementation and promotion across various departments. To address this limitation, future research could investigate the different departments of nurses using healthcare AI as a way to improve the representativeness of the data and the generalizability of the findings. Second, Huo et al. [105] have categorized medical AI into auxiliary and autonomous technologies based on the classification of its applications. Subsequent research endeavours may explore the varying effects of different types of medical AI on nurses' innovation behaviour. Third, the research employed solely a questionnaire survey as the data collection method, which poses limitations in obtaining comprehensive feedback from nurses regarding the actual implementation of medical AI. To address this limitation, future investigations may explore using case studies and experimental methods in the later stages of the study.

Data Availability Statement

The data that support the findings of this study are available from the corresponding author upon reasonable request.

Ethics Statement

The Science and Technology Research Ethics Committee of Anhui University of Science and Technology approved the protocol of this study (Ethical ID: LW-2023-001).

Conflicts of Interest

The authors declare no conflicts of interest.

Author Contributions

Xianmiao Li conceptualized and visualized this study, performed formal analysis and data curation, wrote the original draft and reviewed and edited the manuscript. Qilin Zong conceptualized the study, performed formal analysis and data curation and reviewed and edited the manuscript. Mengting Cheng investigated the study, curated the data and wrote the original draft. All authors have contributed to the final version of the manuscript. Additionally, each author had provided final approval of the version to be published.

Funding

The authors thank Humanity and Social Science Research Project of Anhui Educational Committee (2022AH020053 and SK2020ZD18), MOE (Ministry of Education in China) Liberal Arts and Social Sciences Foundation (21YJC630067), Anhui Province University Excellent Top Talent Training Project (gxyqZD2022033) and Major bidding teaching research project of Anhui University of Science and Technology (2021xjzdz15).

Acknowledgments

AI has not been used in the preparation of this manuscript. The authors would like to sincerely thank all the nurses and relevant departments involved in this study for their understanding and support. The authors thank Humanity and Social Science Research Project of Anhui Educational Committee (2022AH020053 and SK2020ZD18), MOE (Ministry of Education in China) Liberal Arts and Social Sciences Foundation (21YJC630067), Anhui Province University Excellent Top Talent Training Project (gxyqZD2022033) and Major bidding teaching research project of Anhui University of Science and Technology (2021xjzdz15).

Aim. The aim was to explore the association between nursing professional values (NPV) and mental health among registered nurses (RN) in Spain. **Background.** Nursing is a profession rooted in strong professional values, which guide and shape clinical practice and occupational behaviors. NPV should serve as a source of support in situations of great uncertainty. **Methods.** A cross-sectional study was conducted during the remission phase of the second wave of the COVID-19 pandemic (December 2020–January 2021) among a sample of Spanish RN ($n = 420$). NPV were assessed using the Nursing Professional Values Scale (NPVS-R), comprising 26 items grouped into five factors: caring, activism, trust, professionalism, and justice. Perceived stress, anxiety, and depression were measured by the Perceived Stress Scale (PSS-14) and the Hospital Anxiety and Depression Scale (HADS). Adjusted linear regressions were used to estimate b coefficients for the associations between NPV scores and the three mental health indicators. **Results.** The fully-adjusted analysis, including sociodemographic and occupational variables, revealed that higher activism scores were associated with higher scores of stress (b coefficient: 0.46; 95% confidence interval: 0.03–0.88; p value: 0.035), anxiety (0.24; 0.05–0.43; 0.014), and depression (0.19; 0.01–0.36; 0.035). No other NPV was associated with mental health. **Conclusion.** Organizational policies and programs should be established to protect the most activist RNs and to mitigate the potential detrimental effect of activism on mental health at times and/or circumstances of high workloads and personal stress.

1. Introduction

Nurses are one of the occupational groups that present the highest risk of suffering from mental health distress. Contact with illness and suffering, together with working under the clinical uncertainty of most processes, are inexhaustible sources of psychological stressors, emerging from the nature of care itself. The most prevalent mental health issues suffered by nurses are compassion fatigue and burnout [1, 2], which are in turn associated with anxiety and depression [3, 4]. A meta-analysis of 79 studies involving 28,509 nurses from 11 countries found moderate levels of compassion fatigue, which has increased gradually worldwide over the last decades [2]. Another meta-analysis of 61 studies involving 45,539 nurses from 49 countries found an overall

pooled prevalence of burnout of 11.2% among nurses globally [5].

In addition, the physical and psychological stress of providing care in complex occupational environments means that nurses are even more vulnerable to mental health problems. Certain situations and characteristics of the work environment may reduce the mental well-being of nurses, which compromises the quality of care [6]. Work overload, work shifts, high staff turnover, difficulty in reconciling work and private life, or the type of unit are some of the most evident contributing factors [7]. These contributors can trigger physical exhaustion, sleep disorders, headache, osteoarticular pain, difficulty concentrating, and memory losses, among other symptoms, resulting in job withdrawal due to sick leave, absenteeism, and intention to leave [5, 8].

Furthermore, other less-visible characteristics of the nursing profession confer nurses with a greater propensity for mental distress. First, the mismatch between nurses' expectations and the nonideal reality of nursing care (i.e., conflict between vocation and role) [9]. Second, the stereotypes and gender roles around nursing profession, which can prevent the recognition of mental fatigue from caregiving [10].

These circumstances converged and became intensified during the first waves of the global COVID-19 pandemic, with a severe impact on the mental health of nurses around the world. Several literature reviews have provided evidence of the negative impact of the COVID-19 pandemic on relevant indicators of nurses' mental health, such as mental overload, insomnia, anxiety, depression, post-traumatic stress syndrome, and other mental health disorders [11–15]. Other devastating legacies of the COVID-19 pandemic were the overflowing waiting lists that tested the patience and health of users, and the emerging mistrust of the scientific establishment and the healthcare system by large segments of the population, thus increasing the burden on healthcare workers. Conversely, some studies conducted among healthcare students found a positive impact of the COVID-19 pandemic on professional values [16, 17]. Thus, the COVID-19 pandemic provided a unique setting to study the role of certain professional characteristics on nurses' mental well-being [18, 19].

Nursing professional values (NPV) are the principles that govern the nursing discipline which have been agreed upon by different nursing associations worldwide. Professional values provide a nursing moral framework and shape ethical behavior, thereby aiding in complex decision making and maintaining nurses' moral obligation to follow organizational standards and not violate ethical principles [20]. Weis and Schank [21] defined professional values as "standards of action accepted by professionals and professional groups which provide a framework for evaluating beliefs and attitudes that influence behavior". Therefore, in daily professional practice, they provide the basis for care decisions [22, 23]. Although NPVs originate from each region's nursing history, cultural background, social groups, religion, and lived experiences, according to the American Nurses Association (ANA) [24], certain NPVs represent the ethical code of the profession and can be considered universal: altruism, autonomy, human dignity, social justice, and integrity [25]. A conceptual model for NPVs derived from the work of Weis and Schank [21, 25–27], which in turn is based on the ANA Code of Ethics, is shown in Figure 1.

Nurses' awareness of their professional values and how they impact their caring role constitute a central part of humanistic nursing care [28]. Ultimately, strong NPVs should contribute to adequate and safe care [20], even in complex clinical or organizational situations, which increase the physical and psychological demands on nurses. According

to the results of a cross-sectional study in Spain, NPVs were positively associated with compassion satisfaction during the COVID-19 pandemic [29]. We therefore hypothesized that NPVs would allow nurses to manage their levels of stress, anxiety, and depression under highly stressful conditions and work overload. This study aimed to explore the association between NPVs and mental health indicators of registered nurses (RNs) in Spain during the COVID-19 pandemic, specifically analyzing stress, anxiety, and depression.

2. Methods

2.1. Study Design and Participants. A cross-sectional study involving a sample of RNs of Asturias, a region in northern Spain of approximately 1 million inhabitants, with a network of 15 hospitals and 60 primary care centers. A minimum required sample size of 345 nurses was deemed necessary to detect clinically relevant differences in mental health indicators, considering a 3% margin of error and a 95% confidence interval. Participants were recruited through the Official Board of Nurses of Asturias using nonprobabilistic sampling. This institution integrates all the RNs who carry out their professional practice in the region, since professional membership is mandatory in Spain. An e-mail was sent to all the RNs ($N=4,550$), providing detailed information on the study and a link to an anonymous online form containing the study survey. In addition, participants were asked to provide informed consent and confirm that they met the established eligibility criteria when accessing this online form. RNs were included if they worked in any public or private health facility in Asturias and if they had patient contact since the beginning of the COVID-19 pandemic (March 2020). Conversely, RNs on sick leave due to accident, mental or physical illness between March 2020 and January 2021 were excluded. To maximize recruitment, information about the study and the link to the questionnaire were also posted on the institutional website of the Official Board of Nursing of Asturias.

Data collection was performed between December 2020 and January 2021, during the remission phase of the second wave of the pandemic in Asturias, the most severe in terms of cases and deaths of the entire COVID-19 pandemic. In November 2020, dubbed Black November, Asturias recorded the highest 14-day notification rate of the COVID-19 pandemic, with 650 cases per 100,000 inhabitants, which was well above the Spanish average. This month alone accounted for 46% of all COVID-19 deaths in 2020.

Prior to the mass mailing, a pilot test of the procedure and the survey were performed with 40 randomly selected RNs. By the end of the recruitment process, 435 surveys were received. Later, six duplicate records and nine participants with missing data on occupational variables were removed. Therefore, the final sample consisted of 420 RNs, representing 9.3% of the target population. Further details about the study are reported elsewhere [29].

FIGURE 1: Core professional values of nursing according to Weis and Schank [21, 25, 26].

2.2. Ethical Considerations. The study was approved by the Research Ethics Committee of Asturias (ref. 563/2020) and all participants gave informed consent. Participation was voluntary and anonymous. No incentives were offered. Data confidentiality and patient anonymity were preserved in compliance with the Spanish Organic Law 3/2018 of 5 December on Personal Data Protection and Guarantee of Digital Rights. This manuscript follows the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) recommendations.

2.3. Study Variables and Survey Instruments

2.3.1. Nursing Professional Values. NPVs were measured using a reduced version of the Nursing Professional Values Scale (NPVS-R) [26, 30], an instrument derived from the Code of Ethics of the American Nurses Association. The NPVS-R consists of 26 items grouped into five dimensions: caring (9 items), activism (5 items), trust (5 items), professionalism (4 items), and justice (3 items). The importance assigned to each value is scored according to a Likert-type scale of 1 to 5 points, with 1 being “not important” and 5 being “very important.” Weis and Schank supported the

internal consistency reliability of the five factors (alpha coefficients of 0.70 to 0.85) and of the total scale (alpha coefficient of 0.92) [26].

2.3.2. Mental Health. In our study, the mental health of the RNs was assessed by considering the self-perceived level of stress, and symptoms of anxiety and depression. Stress was measured using the Spanish version of the Perceived Stress Scale (PSS-14) [31]. With this tool, each RN assessed the degree of stress that certain day-to-day situations caused them during the month prior to the response. The PSS-14 consists of 14 items with five response options, consisting of 0 “never,” 1 “almost never,” 2 “from time to time,” 3 “often,” and 4 “very often,” although the score of some items must be reversed. The total score ranges from 0 to 56 points, with higher scores indicating higher levels of perceived stress. Cronbach’s alpha coefficient for this study was calculated to be 0.90. Consequently, it was determined that the scale had a high level of reliability for our sample.

Anxiety and depression were assessed using the Spanish version of the Hospital Anxiety and Depression Scale (HADS). This scale consists of two independent subscales of seven items each, which assess anxiety and depression symptoms during

the previous seven days [32, 33]. Each item has four response options, ranging from 0 “absence/minimal presence” to 3 “maximum presence.” Some items must be reversed to obtain the final HADS score. The score for each subscale ranges from 0 to 21 points, with a higher score indicating greater severity of symptoms. In our sample, we obtained an alpha of 0.92, which is considered an excellent reliability.

2.3.3. Potential Confounders. A set of potential confounding variables was generated based on a literature review followed by expert consensus. Sociodemographic data collected in the study included sex (male or female), age (in years), sentimental partner (yes or no), and having children (yes or no). Regarding work variables, the level of education (university degree or postgraduate degree, including master’s or doctorate), type of service (COVID-19 frontline unit, including emergency department, intensive care units and COVID-19 units, or second-line unit, including other services) and work shift (fixed morning, rotating shift or morning on-call) were considered.

2.4. Data Analysis. Statistical analyses were performed using STATA version 19 (StataCorp.; College Station, Texas). First, a Shapiro–Wilk normality test was performed on the data set of each measure and the results indicated that scores followed a normal distribution. Subsequently, linear regressions were used to obtain the b coefficients of the associations between the NPV scores and the three mental health indicators. Positive b coefficients indicated a direct association and negative coefficients indicated an inverse association. To rule out the potential confounding effect of some variables on the associations studied, in addition to a crude model, regression models were run adjusting for sociodemographic variables (age, sex, relationship, and children) and work variables (academic level, unit, and shift). Given that there was a strong correlation between all the NPVs (Table 1), each model was adjusted for the remaining NPVs. For example, when the NPV care was used as an independent variable, the model was additionally adjusted for activism, trust, professionalism, and justice. In this manner, the isolated contribution of each NPV on mental health was studied. Only *p* values <0.05 were considered statistically significant.

3. Results

The social and work characteristics of the sample are shown in Table 2. Most participants were women, aged 35–50 years and without children. Regarding the occupational variables, the most frequent were having completed only a university degree in nursing, second-line positions during the COVID-19 pandemic, and rotating work shifts.

The mean scores (\pm standard deviation) for the five dimensions of the NPVs were: 41.1 points for caring, 20.4 for activism, 22.4 for trust, 17.1 for professionalism, and 13.5 for justice (Table 3). Regarding the selected mental health indicators, the mean score for stress was 27.5 (± 9.71), 8.91 (± 4.39) for anxiety, and 6.66 (± 4.01) for depression.

According to the results of the linear regressions for the association between NPVs and mental health indicators, only activism was significantly and directly associated with stress, anxiety, and depression (Table 4). The higher the activism score, the lower the mental well-being score of the RNs, both in the crude models and those adjusted for confounding variables.

4. Discussion

According to the results of our study, conducted in the context of a situation of maximum clinical and ethical uncertainty, organizational difficulties, and high physical and emotional demands on healthcare workers, the activism of RNs was associated with worse mental health indicators. No other NPV was associated with the mental well-being of RNs.

Our study was the first to examine the association between NPV and multiple mental health indicators, hampering comparison with other studies. Overall, our findings did not support the study hypothesis, as NPVs did not mitigate the negative impact of the pandemic on the mental health of RNs. A plausible explanation is that the mental health of RNs was so affected by the demands of the COVID-19 pandemic that the ability of NPVs to guide clinical practice while maintaining mental well-being was severely reduced. Moreover, contrary to the hypothesis, higher activism scores were consistently associated with lower levels of stress, anxiety, and depression. Activism refers to an active role of RNs in aspects related to resource management, research, and transfer of relevant findings to clinical practice. It also represents the struggle to strengthen the profession and broaden its scope of action, with active participation in professional organizations. In addition, activism is considered necessary for leadership. Therefore, it refers to a conception of the profession that, without neglecting individual-centered care, is oriented towards the global health of populations, and seeks to empower the nursing discipline by participating in health policies [27]. In short, activism is inherent to the nursing profession, since RNs are the advocates and interlocutors of the people in relation to the healthcare system [34]. Although it is not one of the dominant NPVs in normal situations [35], its characteristics may make activism particularly relevant in exceptional socio-health situations that require RNs to take a step forward.

The association between activism and poorer mental health has already been documented by some other authors, who found that activism was related to lower job satisfaction and higher emotional burden and could increase stress and anxiety [36–38]. The reasons that may explain this association are varied. First, the mental and emotional sacrifice demanded by activism may contribute to the onset of anxiety and depressive symptoms [36]. Getting involved in organizational issues and striving to translate recent findings into clinical practice can be mentally challenging and emotionally draining, because it usually pits the activist against management, peers, and one’s own personal limitations. For this reason, building a positive view of activism would help

TABLE 1: Correlation between nursing professional value scores ($n = 420$).

mitigate this deleterious effect. Mundie et al. [39] emphasize the importance of creating support networks for activist RNs as a way to ensure quality, sustainable, and protective nursing care for workers. Second, because activism is time-consuming, highly activist RNs need to put more effort into

direct patient care to meet their expectations, which may contribute to a sense of lack of accomplishment, leading to increased stress and anxiety. Third, activism may be associated with exposure to situations of ethical conflict. Nurses who engage in activism-related initiatives often do so to

achieve improvements in patients' rights or to defend the healthcare system, resulting in situations where ethics clash with the requirements imposed by institutional policies. This is especially relevant in exceptional situations and can trigger moral distress, sadness, and disillusionment at not being able to act according to their value system [40]. When there is a confrontation of the activist RN with the organization or the system, feelings of isolation and stigmatization may emerge, especially if the activist behavior is seen as a threat by management or peers [41].

Of the remaining NPVs included in this study, the only one that showed an association with a significant borderline *p* value was professionalism. In the crude analyses and adjusted for sociodemographic variables, a higher score in professionalism was associated with a lower level of stress. Kim et al. [42] observed a positive link between professionalism and quality of life in RNs, which can be considered a proxy for good mental health. Furthermore, in this study, professionalism was also associated with a better ethical climate and higher compassion satisfaction. In contrast, Gonzalez-Pando et al. have suggested that higher levels of expertise, which indicate active engagement in professionalism, may increase compassion fatigue among frontline nurses [29].

Clearly, all countries must learn to live with health crises, thus, it is imperative to build robust and resilient health systems that also protect their workers through positive work prospects and safe and healthy work environments [18, 19]. Although in this study NPVs were not associated with greater mental well-being, as hypothesized, preserving NPVs should be non-negotiable. A healthcare system that cultivates NPVs will always strive for excellence and safety and will place its staff and users at the center of care. Therefore, although our findings might discourage the promotion of activism, it should still be considered a core value, which strongly supports the precepts of nursing codes of ethics around the world. Indeed, one of the main factors explaining greater activism is having received a higher

quality university education [43]. Rather than attempting to improve the mental health of RNs by curtailing their activism, which would undermine the social and health outcomes of the nursing profession, it would be advisable to have programs to encourage activism in a rational manner and simultaneously design programs for the mental healthcare of the workforce. In addition, a cross-sectional study of 748 nurses from Saudi Arabia found that activism during the COVID-19 pandemic was significantly associated with higher professional competence [44], which may be another compelling reason to promote continuing education programs that emphasize the importance of NPVs.

In general, close monitoring of the psychological status of nurses and its determinants should be part of the ongoing preparedness efforts of health systems worldwide [45]. In addition, there is an urgent need to develop and implement local and national strategies, consistent with NPVs, to help nurses cope with the burden of mental and psychological disorders resulting from the demanding and emotionally draining work of caring for people and communities [46]. With the prospect of emerging health crises, this is an even higher priority.

This study had some limitations. First, the study design was cross-sectional; therefore, it is not possible to know the precise direction of the associations. However, considering the nature of the variables studied and previous scientific literature, the direction proposed in this study is plausible and more likely than the opposite. Second, because of the convenience sampling, the representativeness of the sample cannot be guaranteed. Although the number of responses was sufficient to detect relevant changes, selection bias cannot be ruled out. Respondents to voluntary web-based forms tend to be more interested in the topic of study and younger, which may affect the results. As the survey was delivered at times of high professional and personal demand due to the COVID-19 pandemic, it is possible that RNs with worse mental health indicators, more upset with the organization, and those who are more militant may have

responded, which may have affected our findings. Third, although the associations found regarding activism were statistically significant and consistent across models, they were clinically irrelevant. Finally, some variables of interest for a better understanding of the phenomenon, such as personality factors, were not included; their measurement would have greatly complicated data collection.

5. Conclusion

In conclusion, higher activism scores were associated with worse mental health indicators in Spanish RNs, including higher levels of stress, and symptoms of anxiety and depression. No other NPV was consistently associated with mental health. Organizational policies and programs should be established to protect the most activist RNs and to mitigate the potential detrimental effect of activism on mental health at times and/or circumstances of high work and personal demand. Well-designed studies are needed to test the longitudinal association between professional values and the mental health of RNs, as well as that of other healthcare workers.

Data Availability

The data used to support the findings of this study are available from the corresponding author upon reasonable request.

Ethical Approval

This study was approved by the Ethics Committee on Clinical Research of Principado de Asturias (Spain) (No 2020.563).

Disclosure

The funding agency had no role in the study design, data analysis, interpretation of results, writing of the report, and in the decision to submit the article for publication.

Conflicts of Interest

The authors declare that they have no conflicts of interest.

Authors' Contributions

AL and DG-P conceptualized the study, performed supervision, and proposed the methodology. MG-G and AF-F performed investigation. AL and BS-G performed formal analysis and wrote the original draft. DG-P provided funding acquisition and resources. MG-G and AF-F contributed to validation. MG-G, AF-F, and DG-P wrote, reviewed, and edited the article.

Acknowledgments

This research was funded by a grant from the Official College of Nursing of Asturias (Spain).

Background. Violence at work against healthcare professionals is a frequent and pervasive problem. There are growing data that indicate nurses are especially susceptible to experiencing violent acts at work. Resilience helps strengthen nursing competency in the proper management of stressful circumstances, like being exposed to workplace violence. **Aim.** The aim of the study is to assess the impact of resilience on workplace violence among mental health nurses. **Method.** A cross-sectional research design was used to conduct this study with a convenience sample of 361 nurses recruited from a governmental psychiatric hospital in Saudi Arabia. **Tools.** Data were collected using two tools: the first tool was the workplace violence questionnaire, which collected nurses' demographic, job, and workplace violence data, and the second was the resilience at work scale to assess nurses' resilience. **Results.** This survey found that 70.4% of nurses experienced workplace violence in the last year, and fewer than half were resilient at work. Close to one-third (33.5%) of nurses were terrified and confused after workplace violence. The most violent repercussions were psychological (46.8%): dread, tension, and worry. Additionally, 48.8% of nurses exhibited high work resilience. **Conclusion.** A considerable percentage of mental health nurses encountered instances of violence during the provision of care inside mental health hospital settings. The variables of nationality (non-Saudi nurses), rotating work shift, educational levels, and exhibiting a lower level of resilience were found to have a statistically significant correlation with instances of workplace violence. **Recommendation.** Training programs and educational initiatives should be developed and implemented to equip nurses with the necessary knowledge and skills to effectively respond to and prevent workplace violence incidents. By providing comprehensive training, healthcare organizations can empower nurses to address and mitigate workplace violence, ultimately creating a safer and more supportive work environment.

1. Introduction

Workplace violence poses a significant health concern for healthcare workers globally, including mental health nurses, who are particularly vulnerable to such incidents [1]. Workplace violence is defined as any act of physical abuse, intimidation, harassment, or threatening behavior occurring at the workplace; it encompasses a range of behaviors from verbal abuse to homicide [2]. Among the perpetrators, workplace violence was done by patients' relatives, patients, staff, and management [3].

Healthcare and social service personnel, including nurses, are particularly vulnerable to client violence, which accounts for 30% of all workplace homicides [2]. The prevalence of workplace violence within healthcare settings

is not limited to a single profession but extends across various sectors within the healthcare industry [4]. For instance, studies have reported a high prevalence of workplace violence among healthcare workers, including nurses, physicians, support staff, and paramedics. In the district of Peshawar, Pakistan, the estimated prevalence of workplace violence was found to be 51.0% [5]. Similarly, in northwest Ethiopia, more than half (58.2%) of healthcare workers, including nurses/midwives, physicians, general practitioners, and pharmacists/laboratory staff, reported experiencing at least one manifestation of workplace violence (physical, verbal, or sexual) in the past 12 months [6]. Recent research has also indicated a high prevalence of workplace violence among registered nurses, ranging from 70.0% to 80.0% [7]. Furthermore, a study conducted in upper

Northern Thailand found that the prevalence of physical workplace violence among nurses in the preceding 12 months was 12.1%, while the prevalence of psychological violence included verbal abuse (50.3%), bullying/mobbing (10.3%), and sexual harassment (1.6%) [8]. This elevated risk is attributed to the inherent nature of their roles and frequent interactions with patients, families, and visitors [9]. Workplace violence can occur across various healthcare settings, including hospitals, nursing homes, primary health care setting, and psychiatric facilities [4, 5].

Numerous factors contribute to the risk of workplace violence, including working closely with individuals with a history of violence, social and occupational pressures, organizational policies, employees' psychological attributes, and personal characteristics [10–12]. Nurses, in particular, are at risk due to their close proximity to patients and their families, who may exhibit aggressive behaviors due to illness, injury, or stress [13]. Najafi et al. [14] identified five categories of predisposing factors associated with workplace violence. These factors include unmet expectations of patients/relatives, inefficient organizational management, inappropriate professional communication, factors related nurses as poor stress management and lack of clinical competence among nurses, and factors related to patients, patients' relatives, and colleagues such as mistrust of nurses' job performance and a negative public image of the nursing profession.

Workplace violence has detrimental effects on nurses, leading to decreased job satisfaction, increased absenteeism, and poor service quality [15]. In acute psychiatric settings, nurses face heightened risks of aggression from service users, necessitating the adoption of effective coping strategies and resilience-building initiatives [16].

Resilience, characterized by self-awareness, faith, hope, insight, and self-care, plays a crucial role in mitigating workplace violence among nurses [17]. Developing personal resilience helps nurses to manage stress, preserve job satisfaction, and enhance job performance. Resilience interventions have shown promising results in reducing workplace violence and strengthening nurses' ability to cope with challenging situations [18].

There are several methods that can help nurses build their resilience. Providing comprehensive education and training on stress management techniques, self-care practices, and coping strategies is crucial [19]. Workshops, seminars, and ongoing professional development programs can equip nurses with the necessary tools to navigate difficult situations successfully. Additionally, establishing peer support networks and mentorship programs allows nurses to connect with and learn from their colleagues, fostering resilience through shared experiences and emotional support [20]. Developing emotional intelligence skills, such as self-awareness, empathy, and effective communication, further aids nurses in managing their emotions and responding empathetically to patients and colleagues, thereby enhancing their resilience [21]. Moreover, introducing mindfulness and relaxation practices, such as meditation, deep breathing exercises, and yoga, can also

contribute to resilience by promoting self-awareness, stress reduction, and emotional well-being [22]. Finally, promoting a healthy work-life balance through policies that prioritize adequate rest, time off, and scheduling flexibility is vital for nurses' resilience [23]. By recognizing the value of building resilience in nurses and allocating resources to support these concrete methods, healthcare organizations and leaders can create a more supportive and sustainable work environment that prioritizes the well-being and resilience of nurses.

To my knowledge, the existing research on workplace violence in healthcare has primarily focused on its prevalence, risk factors, and consequences for healthcare professionals in general. However, limited attention has been given to the role of resilience as a potential protective factor when mental health nurses in Saudi Arabia face workplace violence. While resilience has been recognized as a valuable resource for coping with occupational stress and adversity, its specific impact on workplace violence experienced by mental health nurses remains underexplored. Thus, the research gap lies in the need to investigate the relationship between resilience and workplace violence in the context of mental health nursing, providing a deeper understanding of how resilience can contribute to preventing or mitigating workplace violence incidents. This study aims to address this research gap by examining the impact of resilience on workplace violence experienced by mental health nurses.

1.1. Research Questions

- (1) What are the levels of workplace violence and resilience among mental health nurses?
- (2) Is there a relationship between resilience and workplace violence among mental health nurses?

2. Methods

2.1. Research Design and Setting. This study utilized a cross-sectional design to quantitatively assess the prevalence of an outcome (workplace violence) and associate various factors (resilience) at a single point in time. This study was conducted at a large, 530-bed inpatient psychiatric facility in Riyadh, Saudi Arabia. This government-run mental health center serves both adult and child patients from the local community presenting with a range of acute and chronic psychiatric conditions.

2.2. Participants. The present study utilized a convenience sampling method, consisting of 361 mental health nurses. The nurses included in the study were of both genders, had a minimum of one year of professional experience, showed a willingness to actively engage in the research, currently employed, and actively providing direct patient care. On the other hand, nurses with less than one year of clinical experience, part-time nurses, those not currently employed at the mental health center, and nurses occupying administrative or nonpatient care roles were excluded from the study.

2.3. Sample Size. The sample size was calculated using the formula $n = (Z2 * \sigma2)(p)(q)/d2$, where n indicates the required sample size, z is the standardized normal deviation corresponding to $\alpha = 0.05$ and 95% confidence level ($z = 1.96$, for two-tailed), p indicates the expected prevalence based on the previous study [24] ($p = 90.3\%$), q indicates $1 - p$, and d indicates the acceptable margin of error for the mean ($d = 5\%$). Consequently, a minimum sample size of 135 was initially determined, with consideration for an anticipated 10% attrition rate. Subsequently, the minimum required sample size should be 149 nurses. The researcher distributed a total of 406 questionnaires in order to ensure an adequate representation of the population and maintain statistical power. Out of the 406 questionnaires, 45 were found to be incomplete, leaving a total of 361 completed questionnaires for analysis.

3. Tools for Data Collection

3.1. Tool I: Resilience at Work Scale. This study utilized the resilience at work scale, which was adapted from the work of Winwood et al. [25], to assess resilience among mental health nurses. It comprises 17 items that are categorized into six dimensions: living authentically (3 items), finding your calling (3 items), maintaining perspective (2 items), managing stress (4 items), building social connections (3 items), and staying healthy (2 items). The Likert scale score for the nurses' responses was reduced from 7 to 5 points based on the expert opinions and recommendations. The scores on the scale range from 1 (strongly disagree) to 5 (strongly agree). For every negative statement, the score will be reversed. The overall score ranges from 17 to 85. Low resilience is shown by a score between 17 and 39, moderate resilience is shown by a score between 40 and 62, and high resilience is revealed by a score between 63 and 85.

3.2. Tool II: Workplace Violence Questionnaire. This questionnaire was developed by the researcher after reviewing recent literature [26–28]. It consisted of three components. The initial section focused on the demographic attributes of the participants, including variables such as age, gender, marital status, nationality, and experience. The subsequent phase of the study examined workplace data, working shifts, and the presence of workplace violence prevention techniques, including training programs, policies, and safety practices. The third part presents information pertaining to the empirical exposure of individuals to occurrences of workplace violence. The study included several aspects of violence, including its nature, origin, duration of occurrence, individuals responsible for its perpetration, responses to occurrences of violence, and suggestions provided by nurses to mitigate the exposure to such acts of violence.

Seven mental health and community care specialists examined the two instruments for content validity to assess their relevance, clarity, application, question phrasing, and interview duration. Following input, changes were made. Cronbach's alpha assessed tool dependability. The resilience scale's reliability coefficient was 0.82, which indicates strong reliability. A pilot study with 30 nurses tested tool feasibility

and clarity. Therefore, the appropriate changes were made. The pilot study nurses were omitted from the main sample of the study.

3.3. Ethical Consideration and Data Collection. The researcher gained approval from the Committee of Research Ethics at Shaqra University (ERC-SU-S-202400005). A formal correspondence was sent to the research institution to request authorization for the collection of essential data. Following a comprehensive explanation of the study's objective, authorization was obtained from the directors and departmental heads of the designated hospital to proceed with participant recruiting. Following a comprehensive elucidation of the study's objective, the researcher diligently collected signed informed permission from the participating nurses prior to the commencement of data collection. All individuals who took part in the study were provided with a guarantee of both anonymity and confidentiality, which extended beyond the duration of the research. To ensure participant anonymity, stringent, each participant was assigned a unique code that was used to identify their responses and data. This code was not linked to any personally identifiable information, ensuring the confidentiality of their identity. The participants were not provided with cash or monetary incentives for their participation in the study. However, the researcher expressed his appreciation for their involvement through acknowledging their contribution to the research and emphasizing the importance of their participation in generating valuable insights for the field. The importance of participants' voluntary engagement and their entitlement to resign from the research at any given point were also underscored. If a participant chose to withdraw, their data would be immediately removed from the dataset using their unique identifier assigned to the participant. Data collection began in January 2023 and finished in April 2023. After briefly outlining the study's goal and the requirement to gather data, the questionnaire was delivered individually in the study setting.

3.4. Data Analysis. The data that were gathered were systematically arranged, compiled into tables, and subjected to statistical analysis using IBM SPSS, version 23.0. The assumption of normality was acceptable, with categorical variables being expressed in terms of frequency and percentage. The mean and standard deviation were used to represent continuous variables. Binary logistic regression was chosen as the primary statistical analysis technique for predictive modeling with a binary outcome variable (workplace violence coded as 0 or 1). Demographic variables were entered into block 1 to control their potential confounding effects and resilience entered into block 2 in the regression model. A p value less than 0.05 was deemed to be statistically significant.

4. Results

4.1. Distribution of Nurses According to Their Demographic Characteristics and Their Relationships with Exposure to Workplace Violence. The majority of the sample consisted of

young people, with an average age of 30.31 years. The majority of respondents were male (76.5%), married (79.2%), and of Saudi nationality (71.5%). 52.1% of participants possessed a bachelor's degree in nursing. The mean clinical nursing experience in the sample was 9.97 years. The prevailing work patterns identified were regular shifts (63.4%) as opposed to rotational shifts (36.6%) and working non-morning shifts (53.2%) (Table 1).

4.2. Distribution of Nurses Based on Their Exposure to Workplace Violence. A significant proportion (70.4%) of the nurses experienced workplace violence at least once within the past year, mainly verbal, as reported by the majority (67.3%) of them, followed by physical and sexual violence (15.0%, 9.1%, respectively). Moreover, more than one-third (35.2%) of them were exposed to workplace violence three times or more. More than half (59.0%) of participants were exposed to violence in the morning, mainly by patients (45.4%), and the majority of them were exposed to violence by adult (53.2%) and male perpetrators (34.3%). Nearly one-third (33.5%) of the nurses experienced fear and confusion as immediate reactions to workplace violence. Furthermore, the predominant outcomes of violent incidents were psychological effects, specifically manifesting as fear, stress, and anxiety, accounting for 46.8% of cases. A majority of the nurses, specifically 65.4%, reported occurrences of violent situations (Table 2).

4.3. Suggestions from Nurses for the Prevention and Management of Workplace Violence. Strict penalties for violence perpetrators were the most frequent suggestion by more than half (50.7%) of the nurses, followed by adequate staffing to enhance health service quality (45.2%), attending training programs focused on violence prevention and management (38.8%). Additionally, 29.1% of participants indicated prioritizing the enhancement of nurses' qualifications. On the other hand, a minority (6.9%) of the nurses suggested the presence of an effective security system (Figure 1).

4.4. Nurses' Levels of Resilience at the Workplace. Most of the nurses had high levels of resilience in relation to the "living authentically" and "building social connections" domains (87.0% and 82.0%, respectively). Over three quarters of the participants, specifically 76.2 percent, exhibited a high level of resilience in the "finding your calling" domain. In contrast, less than half of the participants demonstrated a high level of resilience in the "staying healthy" and "managing stress" domains, with percentages of 47.9% and 46.8%, respectively.

Furthermore, slightly less than half (48.8%) of the studied nurses had a high total level of resilience at work (Figure 2).

4.5. Predictors of the Nurses' Exposure to Workplace Violence. The association between exposure to workplace violence and the characteristics of the participants was explored using binary logistic regression analysis (enter method), with exposure to workplace violence as the dependent variable. The overall model was statistically significant, $\chi^2(11) = 53.95$,

$p < 0.001$, indicating the predictors as a set reliably distinguished between exposure groups. The Cox & Snell R square was 0.139, suggesting that the predictors collectively explain about 13.9% of the variation in the nurses' exposure to workplace violence. Only four variables were found to be predictors of exposure to workplace violence such as nationality, education, work rotation, and resilience at work. The ORs (95% CI) for the nationality (reference: Saudi) were 0.55 (0.32–0.95). The ORs (95% CI) for secondary school education, technical institute, and bachelor's degree were 3.79 (1.30–11.02), 3.94 (1.08–14.40), and 2.92 (1.03–8.21), respectively. The ORs (95% CI) for work rotation types and resilience were 2.41 (1.15–5.05) and 0.92 (0.89–0.95), respectively (Table 3).

5. Discussion

The present study had two objectives: firstly, to evaluate the prevalence of workplace violence and resilience among mental health nurses; secondly, to delve into the intricate relationship between resilience and the perception of workplace violence among mental health nurses.

The findings of the current survey indicate that more than two thirds (70.4%) of the nurses reported instances of workplace violence over the last year. This finding comes in line with the results of Basfir et al. [24] who found that the prevalence of workplace violence among mental health nurses was 90.3%, alarming that nurses experience such a high level of violence. Furthermore, the finding of the present study noted that verbal violence was the most common type of violence experienced by most nurses, followed by physical violence. Similar findings were reported by Sun et al. [29] and Ferri et al. [30] who found that the most frequent type of violence was verbal abuse. Moreover, the current study found that the less common type of workplace violence was sexual violence (9.1%). This might be attributed to the fact that sexual violence and assault are deplorable actions across different communities and go against both the law and religious principles. This is supported by the results of Harthi et al. [31] who noticed that the rate of sexual harassment was lower than those reported in other countries and justified this lower prevalence of sexual assaults due to the nature of the Saudi community and its compliance with religious values and rules. Additionally, numerous effects of workplace violence have been documented in several studies, and these effects significantly affect employees' physical and mental health as well as their productivity and level of customer service [32, 33].

The study findings reported less than half of nurses (46.8%) indicated that they experience psychological effects resulting from their exposure to workplace violence. Additionally, a smaller proportion (17.7%) reported changes in work performance, including absences and decreased productivity, which can significantly affect the quality of care delivered. These findings disagreed with Small et al. [34] who reported that most of the participants were under-reporting workplace violence incidents, mainly because of their unawareness of the availability of such policies and not receiving training in the workplace. From the results of the

present study, it could be observed that around half of the studied nurses were exposed to workplace violence three and more attacks in the last year. The study's findings supported with Clari et al. [35] and Sisawo et al. [36] who reported that most health care workers experienced three and more violent events. Like many studies, the patients and their relatives were frequently reported as the main perpetrator of violence toward nurses [3]. This might be accounted for by the fact that nurses are frequently the first-person that patients and their families meet and have more direct interactions with them. They are frequently held responsible for late or subpar health services. As a result, they take the brunt of patients' unruly behavior, their relatives' dissatisfaction with the care they receive, and/or the confusing hospital rules that outsiders are expected to follow. In a sense, nurses end up being the scapegoat. Additionally, nurses who are understaffed and compelled to hurry care increase patient and family dissatisfaction with the care they receive, raising the risk of violence in the workplace [37].

Unfortunately, the current study noted that less than half of the studied nurses reported occurrence of violent acts from their coworkers such as physicians, nurses, and supervisors. This is not what one would expect, as a safe environment should be provided for both patients and the

coworkers themselves in a health care setting that is free from threats of violence. In the same context, the result of Ope-babadele and Ilesanmi [38] found that physicians and supervisors were among the sources of workplace violence against nurses.

Furthermore, the results from the current study highlight that nurses who were working rotating shifts and evening and night shifts reported more exposure to violent attacks. This finding aligns with the research conducted by Sun [29], which revealed a correlation between heightened risks of work-related violence and nurses who were assigned to evening, night shifts, and rotating day schedules. This may be due to inadequate security and having fewer nurses' numbers in comparison to the morning shift creating an environment that is conducive to violence. For instance, the study of Chaiwuth et al. [8] found that risk factors for verbal abuse included being a registered nurse with direct nursing care responsibilities; workplaces without adequate security; and having workplace violence concerns. Moreover, the study of Basfr et al. [24] found that the time of violence, source of violence, patient dissatisfaction with medical care, and lack of organizational support for nurses were significantly associated with the occurrence of workplace violence in psychiatric units.

#Respondents could select more than one answer.

The current study found that the majority of the nurses exhibited either high or moderate levels of resilience, indicating their ability to effectively cope with and adapt to workplace challenges. These findings align with the results of an integrative review study conducted by Bui et al. [1], which examined the resilience levels of mental health nurses. The review study found that mental health nurse resilience tends to be moderate to high. Also, a literature review study of foster et al. [39] found that resilience in mental health nursing is most often moderate, with positive correlations with hardiness, self-esteem, life and job satisfaction, and negative correlations with depression and burnout. However, the study of Zheng et al. [40] conducted at the Institute of Mental Health in Singapore demonstrated that psychiatric

nurses have a moderately low level of resilience. Delgado et al. [41] reported that mental health nurses in Australia had high level of resilience.

From the results of the present study, it could be observed that nurses with high level of resilience are less exposed to workplace violence. This could be attributed to the fact that resilience is seen as a person's positive and constructive responses to stressful situations to promote healthy behaviors. These findings supported by the study Alonazi et al. [42] found that higher resilience levels were associated with higher levels of compassion satisfaction and lower levels of secondary traumatic stress among mental health nurses. Furthermore, an integrative review study of Bui et al. [1] demonstrated that resilience was positively associated with psychological well-being, post-traumatic growth, and compassion satisfaction and negatively associated with burnout, mental distress, and emotional labor among mental health nurses. Notably, Yang et al. [43] emphasized the importance of prevention, de-escalation skills, effective coping strategies, and communication skills in reducing workplace violence among mental health nurses. Similarly, Fida et al. [44] conducted a time-lagged study that highlighted the protective role of relational occupational coping self-efficacy in shielding nurses from workplace incivility, burnout, mental health issues, and turnover intentions. Furthermore, Hsieh et al. [45] demonstrated that personal strength, social competence, and a structured approach serve as protective factors against depressive tendencies in emergency department nurses exposed to workplace violence. Building on these findings, Lozano et al. [12] conducted a systematic review, revealing a significant association between workplace violence and burnout symptoms among nurses and physicians. They identified risk factors such as structural and personal factors, while highlighting the role of a quality work environment and effective coping strategies as protective factors. In the context of healthcare, Morphet et al. [46] conducted a systematic review that underscored the effectiveness of consumer risk assessment, staff education, and aggression management teams in reducing workplace violence. However, their findings indicated no evidence to support the efficacy of zero tolerance policies, incident reporting, and duress alarms. Furthermore, d'Ettoire et al. [19] emphasized the importance of prioritizing training, improved communication skills, accurate reporting, and optimized workplace design in minimizing stressful conditions in waiting rooms to effectively manage workplace violence against healthcare workers in emergency departments. Additionally, Hsieh et al. [47] identified higher family support as a key protective factor against the development of depressive symptoms among assaulted psychiatric ward nurses.

5.1. Limitations of the Study. This study had several limitations. Firstly, the findings may lack generalizability to broader populations of healthcare workers or other settings due to the homogeneity of the sample. The exclusive focus on mental health nurses limits the extrapolation of results to healthcare professionals in different specialties or roles who

FIGURE 1: Suggestions from nurses for the prevention and management of workplace violence. Respondents were allowed to select multiple options.

may face distinct risk factors for workplace violence. Moreover, employing convenience sampling introduces potential selection bias, as participants may not be representative of the entire population of interest, leading to skewed findings and decreased external validity. Additionally, the use of a cross-sectional design restricts the ability to establish causal relationships between variables, as it provides only a snapshot of data at a single point in time, precluding longitudinal assessment of trends and changes over time. Therefore, future research endeavors should strive for greater diversity in samples, employ more rigorous sampling methodologies, and consider longitudinal or mixed-methods approaches to enhance the robustness and generalizability of findings regarding workplace violence in healthcare settings.

5.2. Implications for Practice. Based on the research findings, it is evident that workplace violence is a significant concern among mental health nurses, with a majority of them reporting incidents of violence within the past year. The study findings also indicate that the level of resilience among these nurses ranged from moderate to high. This suggests that while some nurses demonstrated moderate resilience levels, others exhibited higher levels of resilience. The varying range of resilience levels highlights the diversity among nurses in their ability to adapt and cope with the challenges they face in their roles. It is also important to note that resilience plays a crucial role in protecting nurses from the negative effects of workplace stressors, including violence. The study emphasizes the need for healthcare administrators and policymakers to address the issue of workplace violence and prioritize interventions aimed at enhancing resilience among mental health nurses. By investing in initiatives that promote resilience, healthcare organizations can better support nurses in coping with workplace challenges and mitigating the psychological consequences of violence.

6. Conclusion

Based on the results of the present research, it can be inferred that most of the nurses surveyed had occurrences of workplace violence over the last year. This observation is particularly concerning as it reflects the challenges and risks faced by healthcare professionals in their daily work environment. Furthermore, fewer than half of the participants exhibited a high degree of resilience, while the remaining individuals demonstrated a moderate level of resilience. Resilience plays a key role in protecting the negative effects of workplace stressors, including exposure to violence and aggression. The relatively low level of resilience among mental health nurses suggests a potential vulnerability that declares attention from healthcare administrators and policymakers. Furthermore, a noteworthy inverse relationship was seen between the level of workplace violence experienced by nurses and their level of resilience. This finding highlights the importance of fostering resilience among mental health nurses as a protective factor against the negative impact of workplace violence. Nurses with higher levels of resilience may be better equipped to cope with the stressors associated with their profession.

Objective. This study aimed to evaluate the impact of the shared governance model application on the level of perceived professional governance among clinical nurses in a tertiary hospital in Riyadh. **Background.** Professional governance continues traditional governance, shared governance, and self-governance. Shared governance (SG) is the engagement of clinical nurses in decision-making at different levels. This empowers nurses, increases job satisfaction, improves clinical outcomes, and enhances patient satisfaction. **Methods.** This randomised control trial in which researchers distributed the Index of Professional Nursing Governance (IPNG) to a random sample of 440 nurses working in a 1200-bed tertiary hospital in Riyadh and divided into experimental and control groups. The intervention included designing and implementing a nursing shared governance model at the hospital level; professional governance was measured before and eight months after implementation. The IPNG was used to measure nurses' perceived level of professional governance before and after the intervention. The sample was divided into experimental and control groups. **Results.** By comparing experimental and control groups, there was no statistically significant difference between them regarding professional governance subscales and the total IPNG scores before the intervention. At the same time, there was a considerable difference between them after the intervention. Moreover, the scores of the six professional governance subscales and the overall IPNG scores significantly increased after the intervention in the experimental group. They showed no significant difference in the control group. **Conclusion.** Designing and implementing specific shared governance structures and processes effectively enhanced nurses' perceived level of shared governance at the hospital, as evidenced by significantly higher postintervention IPNG scores. Elements of the shared governance model that proved effective included engaging nurses in decision-making at various organizational levels and empowering their involvement.

1. Introduction

1.1. Background. Shared governance is a professional practice model that decentralizes decision-making in healthcare organizations by engaging frontline clinical nurses in a structural framework for participating in

organizational oversight, policy setting, and other administrative functions that directly impact their practice and work environment. The key principles of shared governance include empowering nurses through a collaborative management structure that gives them authority and control over practice-related decisions while also fostering a greater

sense of responsibility and accountability. At its core, shared governance aims to actively engage staff nurses beyond their traditional clinical roles by providing opportunities to have a meaningful voice and influence in the organizational decisions that govern their profession [1, 2].

Moreover, professional governance is a broader term involving the continuum of traditional, shared, and self-governance. Control over practice and resources moves gradually from management to clinical nurses in this continuum. The Index of Professional Nursing Governance (IPNG) is a valid and reliable tool used to measure it [3]. Previous research has shown the advantages of shared governance in nursing in the past few decades; it has been applied in various ways to hospital nurses. Improved nurse retention, work satisfaction, nursing-sensitive indicators, and patient satisfaction were some of these advantages [4–9].

Building a culture of shared governance supports nurses to be effective in decision-making, reducing centralisation in decision-making, increasing confidence and accountability, and creating a collaborative relationship between nurses and other healthcare professionals [10]. This is expected to enhance outcomes for nurses and patients [3, 11]. The shared governance framework is usually applied by moving from a hierarchical to a councillor model, which enhances the involvement of clinical nurses in decision-making [12].

1.2. Theoretical Framework. Kanter's theory of structural empowerment is considered a theoretical basis for nursing governance. According to the idea, structurally empowered nurses can achieve more due to their access to information, resources, support, and development opportunities [13, 14]. The theoretical underpinning of structural empowerment through shared governance models is directly linked to improved nursing and patient outcomes. This relationship between empowerment structures and positive results forms the basis of the Magnet recognition program developed by ANCC for hospitals in the US. While Saudi Arabia does not have an equivalent national accreditation system akin to Magnet, implementing shared governance principles aligned with Kanter's empowerment theory could still yield benefits seen in other contexts. The aim of this study is to explore if introducing shared governance councils in a Saudi hospital impacts nurses' perceptions of professional autonomy and influence, as measured by the IPNG tool, even without the external incentive of Magnet designation. Clarifying this connection and focus on potential internal outcomes rather than accreditation would better contextualize the rationale for the study within the Saudi healthcare system [7, 8].

Furthermore, structural empowerment is one of the main components of the Magnet® Model, and this Model is considered the heart of the American Nurses Credentialing Center (ANCC) Magnet® Recognition Program [15]. Magnet® hospitals or hospitals preparing for Magnet® apply this Model and usually implement shared governance frameworks to enhance nurses' involvement and improve outcomes related to nurses and patients [8, 9, 11]. There are three Magnet hospitals in Saudi Arabia, but several are still

on their journey toward Magnet® [16]. Studies investigating the effect of implementing the shared governance model on nurses' professional governance level are limited. This research has addressed how nurses' engagement in shared governance structures and processes significantly increase their professional governance. Kanter's theory of structural empowerment serves as the theoretical basis, proposing that empowering organizational structures like shared governance lead to greater job satisfaction and effectiveness. By decentralizing decision-making and giving nurses governance council roles, shared governance aims to structurally empower frontline staff. This study hypothesizes that implementing such a model will increase nurses' perceived professional governance as measured by the IPNG tool, in line with Kanter's empowerment concepts.

1.3. Research Question

- (1) What is the impact of the shared governance model application on the level of perceived professional governance among clinical nurses in a tertiary hospital in Riyadh?

2. Materials and Methods

2.1. Study Design. This study employed a randomized control trial design to evaluate the impact of implementing a shared governance model on nurses' perception of professional governance.

2.2. Study Groups. This randomised control trial measured the level of professional governance among a control group and an experimental group of clinical nurses before applying shared governance structures and processes in the hospital and 8 months after the implementation. Nurse participants were engaged in the shared governance model through participation in the main shared governance councils or unit-based councils (UBCs).

2.3. Inclusion Criteria. The inclusion criteria selected clinical nurses working at the tertiary hospital in Riyadh, Saudi Arabia. The nurses needed to have a minimum of three months of clinical nursing experience in order to have adequate exposure to the clinical environment. All participating nurses were also required to be permanently licensed. Another inclusion requirement was that nurses provided informed consent after being made aware of the study's aims and objectives. Only those nurses who completed both the preintervention and postintervention questionnaires, which assessed perceptions of professional governance before and after the implementation of the shared governance model, respectively, were fully included. By limiting inclusion to clinically active and experienced nurses who consented and could have their perceptions measured both longitudinally, the criteria aimed to comprise a sample population most appropriately suited for the study.

2.4. Exclusion Criteria. Nurses were excluded if they had less than 3 months of clinical experience, as they were still new to the clinical setting. Additionally, nurses who did not provide direct patient care, such as those in solely administrative roles, were excluded. Nurses who were on extended leave during the 8-month study period or who could not understand or speak English sufficiently to complete the English questionnaire were also excluded.

2.5. Study Participants. For this randomised control research, 440 clinical nurses from a variety of specialties were selected using a systematic random sampling process. The estimated sample size was determined using the Power Primer with a medium effect size, power of 0.80, and of 0.05 [14]. Using Microsoft Excel, randomisation was carried out by choosing every tenth nurse from a list of 2206 nurses. A permanent licensed nurse with a clinical employment in any hospital and at least three months of experience was the basis for recruiting the participants. Before receiving consent, the participants were informed of the study's aims and objectives. Before and after the intervention, the recruited nurses willingly consented to express their opinions. The initial sample size selected was 440 clinical nurses through systematic random sampling. However, attrition occurred over the course of the study. In the experimental group, 16 nurses withdrew participation and an additional 4 only partially completed the postintervention questionnaire, reducing that group's final sample to 200 nurses. In the control group, 19 nurses withdrew from the study, resulting in a final sample of 200 nurses who completed questionnaires at both time points. In total, the final sample size that completed the study was 200 nurses in each control and experimental groups, for a total of 400 nurses.

2.6. Study Setting. The study took place in a tertiary hospital in Riyadh, Saudi Arabia. A random sample of 440 clinical nurses from different specialties was recruited for this study and divided equally into two control and experimental groups. The research was conducted over eight months in three phases (see Figure 1). In phase 1, the researchers assessed the baseline level of professional governance among the nurse participants in the two groups using a questionnaire tool. In phase 2, the shared governance model, including structures and processes, was applied, and the experimental group nurses were supported to participate in the shared governance councils. In phase 3, the researchers reassessed the level of professional governance among the participants who participated in phase 1. 16 nurses withdrew from the experimental group, and four participants were also excluded from the experimental group because they only partially answered the study questionnaire. In addition, 19 nurses were excluded from the control group because they withdrew in phase 3.

2.6.1. Model Implementation. The design of the nursing shared governance model (see Figure 2) was derived from references related to the American Nurses Credentialing

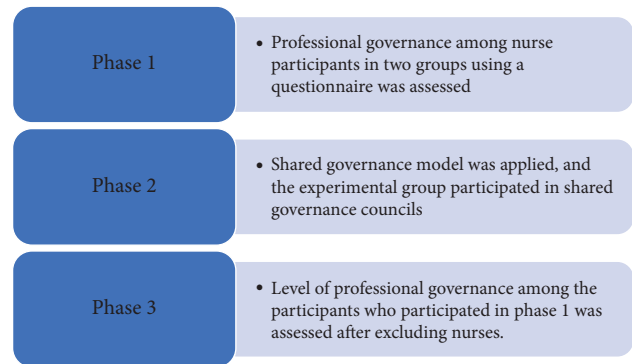

FIGURE 1: Phases of model implementation (source: author).

FIGURE 2: Shared governance model (source: author).

Center (ANCC) as well as the published shared governance experiences by Magnet hospitals and experts [12, 17–21]. The Model included seven main shared governance councils; the practice council, quality and patient safety council, education and professional development council, recruitment and retention council, research and evidence-based practice council, leadership council, and unit-based council (UBC) chairperson's council. The study selected a shared governance model from Magnet hospital literature and aligned with Kanter's empowerment theory, matching the theoretical framework. While not a Magnet facility, the hospital structure mirrored those achieving positive shared governance outcomes through councils empowering frontline involvement in decisions. Prior to implementation, staff reviewed the model for local relevance, customizing as needed. Its representation of staff and collaborative decision-making directly addressed assessing governance perceptions. Together, these links adequately justified applying this conceptual model to evaluate the intervention's influence.

In addition, a unit-based council (UBC) was developed in each nursing unit. The number of nurse members in each main shared governance council or UBC ranges from 5 to 12 members based on the capacity of the nursing unit. Furthermore, commonly shared governance bylaws were developed to regulate the hospital's structures, processes, and pathways of shared governance. This included the path and support of the ideas for improvement (IFIs) submitted by the UBCs. A charter was developed for each council to clarify the scope and main functions of the committee. The leadership council coordinated the efforts of the main shared governance councils and was led by the chief nursing officer. In addition, the main shared governance councils were led by senior nurse managers. However, the UBC chairpersons, members, and members of the main shared governance councils were clinical nurses.

Nurse managers and clinical nurses attended extensive awareness sessions about shared governance, including the new shared governance model, structures and processes, and the benefits of participating in shared governance councils for clinical nurses and the hospital. These awareness sessions helped introduce this major change to the clinical nurses. They motivated many of them to join the committees despite the current challenges of the nursing shortage and high workload. In addition, the sessions helped improve the tendency of nurse managers to maintain control of decision-making. Head nurses and nurse managers were encouraged to attend the UBC meetings as nonvoting members. Moreover, they supported the UBC members by facilitating their meetings and providing them with their time in shared governance activities. The experimental group nurses attended the awareness sessions and were motivated to participate in the main shared governance councils and the UBCs.

2.6.2. Data Collection. The questionnaire started with a demographic profile section. It was designed to encourage nurses to disclose their personal information related to this study to promote their completion of the questionnaire [22]. This section included questions for age, gender, marital status, length of service in a nursing career, working unit, size of service in the current working team, and highest educational qualification.

The Index of Professional Nursing Governance (IPNG 3.0) short form was used in this study. The tool was developed by Robert Hess (1998) and has been widely used to measure professional governance among nurses [23].

The IPNG includes six subscales and 50 items measuring nurses' governance perception. The overall score categorises governance as traditional governance when the total score ranges from 50 to 100, shared governance when the total score ranges from 101 to 200, and self-governance when the total score ranges from 201 to 250. This instrument uses a five-point Likert scale, which includes score 1 as nursing management/administration only, score 2 as primarily nursing management/administration with some staff nurse input, score 3 as equally shared by staff nurses and nursing management/administration, score 4 as especially staff nurses with some nursing management/administration and

score 5 as staff nurses only. Scores 1 and 2 reflect that decision-making is dominated by management/administration. Scores of 4 and 5 indicate that nurses participate more in decision-making.

The IPNG 3.0 short version contains six subscales of professional governance. First, nursing personnel assesses who controls nursing personnel and related structures, including 12 items. Second, information assesses who accesses the information related to governance activities and includes nine items. Next is the Resources subscale, which measures who has influence over hospital resources and consists of nine things. This is followed by the subscale of participation, which assesses who participates in shared governance structures at the unit and hospital levels and includes eight items. Next is practice, which measures who has control over the professional course and consists of seven things. Finally, the dimension of Goals contains five items, which assess who sets goals and negotiates conflict solutions. Data collection used the English version of the tool since the English language is the official language in the hospital and is used in communications, meetings, documentation, and handoff. The test-retest reliability test showed good reliability ($r = 0.857$), and internal consistency reliability was excellent ($\alpha = 0.966$). The applied longitudinal design may affect the recall bias of the nurse participants, but this was minimised by shortening the period between study phases.

2.6.3. Data Analysis. Data analysis was performed using the SPSS® software version 25 through the descriptive statistical measures of frequency distribution, mean, and standard deviation. Normality was assessed via the Kolmogorov-Smirnov test, which was insignificant ($p > 0.05$). Therefore, the parametric tests were applied for data analysis. To verify the study intervention, independent samples *t*-test and paired sample *t*-test were performed to compare the scores of professional governance subscales before and after the intervention. The significance level was set at less than 0.05.

2.7. Ethical Considerations. The Institutional Review Board of King Saud Medical City authorised the research. The IRB Registration Number with KACST, KSA is H-01-R-053. The hospital administrators and nursing department heads within the same health organisations also endorsed the visits. Each participant received a cover letter detailing the instruments' purpose, significance, content, instructions, and completion time. After reading the cover letter, each individual who agreed to participate in the study completed the informed consent form. Participants were free to quit the study at any time without penalties since participation was entirely voluntary.

To protect confidentiality, identifying information was removed from surveys before data entry and each participant was assigned a unique study ID number. Electronic data files and physical consent forms/surveys were securely stored in locked cabinets with limited access for research staff only. Final deidentified datasets did not contain any direct identifiers to allow for anonymous analysis and reporting of aggregate findings.

3. Results

3.1. Reliability. The IPNG Total Score and Factor Subscales were assessed for internal consistency using the test-retest reliability test. Table 1 demonstrated excellent reliability and the internal consistency of all the components, including personnel ($r = 0.962$), information ($r = 0.957$), participation ($r = 0.953$), and goals ($r = 0.949$), as Cronbach alpha value ranged from 0.8 to 0.89, the internal consistency and dependability of resources ($r = 0.860$) and practice ($r = 0.872$) were both good.

3.2. Comparison of Demographic Variables between the Two Groups. Most nurse participants were females, in the age group of 31 to 40 years, had a bachelor's degree, had an overall experience of between 6 to 10 years, and had experience in the current working unit between 1 and 5 years. In terms of the operational teams, they were equally divided between critical care units and noncritical care units. By comparing the demographic variables between the experimental and control groups, results indicate there was no significant difference between them ($p > 0.05$) (Table 2).

In Table 2, shared governance ranges are specified for each professional governance subscale and the overall professional governance score. For the level of professional governance measured for the nurse participants before the intervention for both groups, the mean professional governance scores were almost on the lower shared governance limits for each of the subscales except for personnel and participation subscales which were lower than the shared governance zone (traditional governance). Independent samples *t*-test was used to examine the difference between the two groups before and after intervention regarding professional governance subscales and the overall IPNG scores. Results show that difference between the two groups in terms of professional governance subscales is not significant and the total IPNG scores before the intervention ($p > 0.05$). However, the mean scores after intervention for the experimental group are significantly higher than those for the control group for all professional governance subscales and the total IPNG scores ($p < 0.001$).

3.3. Impact of the Shared Governance Model on Perceived Professional Governance among Clinical Nurses before and after Intervention. Both independent and paired sample *t*-test was used to compare the scores of the professional governance subscales and the total IPNG scores before and after the intervention. Mean scores of professional governance subscales and the full IPNG scores show no statistical significant difference before and after the intervention for the control group ($p > 0.05$), while the scores increased significantly for the experimental group after the intervention for the subscales as well as the total IPNG scores ($p < 0.001$) (Tables 3 and 4).

4. Discussion

The hospital of this study has several multidisciplinary committees that make decisions on issues related to their scope. Members of these committees are usually leaders and

TABLE 1: Internal consistency of the IPNG total score and factor subscales.

	Items	Cronbach's alpha (r)
Total instrument	50	0.979
Factor subscales		
Personnel	12	0.962
Information	9	0.957
Resources	9	0.860
Participation	8	0.953
Practice	7	0.872
Goals	5	0.949

managers, with minimal involvement of clinical nurses. However, the new shared governance structures and processes considerably involved clinical nurses enormously and supported them to be involved in making decisions related to their practice. These nurses were supported to receive, review, and discuss data related to their unit, including nursing-sensitive indicators, patient satisfaction, and nurses' job satisfaction.

The findings of this study showed that the baseline professional governance scores among clinical nurses were at the lower shared governance limits for the majority of the professional governance subscales as well as the overall scores. This is consistent with the findings of studies conducted in Saudi Arabia, Jordan, Lebanon, Egypt, and the United States [8, 9, 11, 24–26].

The mean scores of professional governance subscales after the intervention for the experimental group are significantly higher than those for the control group. In addition, the mean scores of professional governance subscales after the intervention are considerably higher than the mean scores before the intervention for the experimental group ($P < 0.001$). This indicates that the professional governance perceptions of clinical nurses improved after implementing the shared governance model and engaging nurses in the shared governance councils and processes. These findings confirm to a longitudinal study conducted in the US, in which the researchers measured professional governance among nurses in 2013, 2015, and 2017 using the IPNG [26].

Since the hospital had no proper shared governance structures in the first two surveys, results showed total governance scores of 168.62 and 168.39 using IPNG 2.0, below the shared governance zone. After applying better-shared governance structures, the entire shared governance score was 103.84 using IPNG 3.0 within the shared governance zone. Therefore, measuring shared governance among nurses, especially when changes occur, is recommended. Implementing a shared governance model improves nurses' perceptions of professional authority and enhances the culture of shared governance.

This study's findings also confirm the results of a quasi-experimental study conducted in the US, in which the scores of shared governance dimensions increased significantly after enhancing shared governance structures and processes [19]. The interventions included (1) interprofessional strategic planning retreats every six to eight months, (2) celebrating shared governance achievements

TABLE 2: Comparison of demographic variables between the two groups.

Variable	Scale	Experimental group	Control group	<i>p</i> value (>0.05)
Age (year)	21–30	51 (25.5)	50 (24.9)	>0.05
	31–40	86 (43)	84 (41.8)	>0.05

annually, (3) developing three new unit-based councils as part of the hospital's shared governance structure, (4) increasing nurses' access to the hospital library as well as shared governance paid time, (5) enhancing nurses' involvement in budgeting, and (6) submitting annual goals and quarterly progress reports to the coordinating council, and training the councils so they can conduct effective, shared governance meetings. Moreover, according to a longitudinal study in which professional governance perceptions among clinical nurses were measured in 2012 and 2015, professional governance increased after enhancing the shared governance model and allowing nurses to participate in decision-making on different levels [27].

Once the shared governance model was designed and approved, it was announced to all nurses. In addition, nurse managers and clinical nurses attended extensive awareness sessions about the Model and the pathways. Moreover, the

availability of unit-level data was helpful for the UBCs to ensure that their IFIs were data-driven. Furthermore, head nurses and nurse managers facilitated the UBC meetings, attended the meetings as nonvoting members, and supported clinical nurses by giving them the time they spent in shared governance activities back to them. This helped support shared governance and was consistent with the findings of the study conducted in Finland to describe factors that support or obstruct shared administration. Semistructured interviews revealed nurse managers' support, enthusiastic personnel, and neighbouring universities supported shared governance. However, blocking factors included lack of time, poor understanding, and insufficient skills [28]. When clinical nurses are engaged in shared governance, and their ideas of improvement are supported, improvement is expected in nursing-sensitive indicators, patients' satisfaction, and nurses' job satisfaction [6–8].

5. Strengths and Limitations

One of the key strengths of the study is that it provides practical implications and solutions for designing and implementing shared governance structures and processes to enhance shared governance among clinical nurses. Furthermore, the main shared governance councils and the unit managers supported their ideas for improvement. Since the hospital was in the early stages of its journey toward Magnet®, hospital leaders were committed to applying a shared governance model to reap its benefits for patients and nurses. The sample was predominately female, reflecting the typical gender bias of this research and accurately representing the target demographic. Using a self-reported questionnaire raised the possibility of prejudice and impaired the impartiality of the nurses' replies. Yet, the researchers used an experimental design, random sampling, and a valid and reliable tool to assess clinical nurses' perspectives of professional governance. In addition, the research validated the use of a focused intervention to improve shared governance and presented a replicable model.

6. Conclusion

This study evaluated the effectiveness of the shared governance model's implementation among clinical nurses on their perceived level of professional governance. The Model's performance effectively improved the shared governance level among clinical nurses. These findings are of great value for hospitals struggling with lacking or ineffective shared governance structures. Applying the shared governance model successfully improved the six dimensions of professional governance among the nurse participants. A more extensive expansion to this study would be to measure the impact of shared governance on nursing-sensitive indicators, patient satisfaction, and nurses' job satisfaction.

7. Implications

The results of this study indicate that implementing a shared governance model can significantly empower nurses and increase their perceptions of professional autonomy and involvement in decision-making. By establishing formal councils and unit-based committees that give clinical nurses a strong voice, shared governance appears to foster increased collaboration between frontline staff and managers. When nurses feel respected and that their perspectives directly impact important areas like patient care, staffing, and quality improvement, it can boost morale and retention. This is highly relevant for other healthcare organizations aiming to combat issues like heavy workloads and shortages that undermine the nursing workforce. In the future, longitudinal measurement of governance perceptions may show that significant change can be achieved through carefully designed shared governance frameworks that make use of the tools and procedures this study has shown to be successful. Overall, restructuring toward shared models of nursing leadership holds promise for advancing practices that better engage and support bedside clinicians.

Data Availability

The data used to support the findings of this study are available from the corresponding author upon request.

Ethical Approval

Ethical approval for this study was received from King Saud Medical City (IRB), Riyadh with IRB Registration Number with KACST, KSA: H-01-R-053 and IRB Registration Number U.S. Department of HHS IORG #: IORG0010374.

Conflicts of Interest

The authors declare no potential conflicts of interest concerning this article's research, authorship, and publication.

Authors' Contributions

All authors have contributed significantly and agree with the content of the manuscript.

Acknowledgments

The authors thank all nurse participants and those who assisted in this study.

Background: High turnover rates and burnout are prevalent issues among registered nurses in public hospitals in Hong Kong. Pay level satisfaction is one of the crucial factors influencing organisational and professional turnover intention. Understanding whether pay level satisfaction can mitigate the negative impact of burnout on turnover intention can provide insights into the role of financial rewards in employee retention.

Objective: This study aims to evaluate the relationship between job demands and turnover intention among registered nurses in Hong Kong public hospitals. Additionally, it seeks to examine the mediating role of burnout and explore the potential moderating effect of pay level satisfaction on the relationship between burnout and turnover intention.

Methods: The study was a cross-sectional online survey of public hospital staff in Hong Kong. A total of 502 registered nurses who had worked at their employing facility for at least 6 months participated in this cross-sectional survey. Study variables included work overload, job stress, work–family conflict, family–work conflict, conflict with other nurses, burnout, pay level satisfaction and turnover intention. The collected data were analysed using bivariate Pearson correlation analysis and mediated moderation analysis with the PROCESS macro in SPSS 28.0.

Results: Burnout mediated the relationship between job demands, including work overload, job stress, work–family conflict, family–work conflict and conflicts with nurses, and organisational and professional turnover intention. Pay level satisfaction did not exert a moderating influence on the relationship between job demands and turnover intention through burnout mediating this relationship.

Conclusions: The importance of addressing job stress and burnout to mitigate turnover intention and promote nurse retention is underscored. Contrary to expectations, pay level satisfaction did not buffer the negative impact of job demands on turnover intentions via burnout. This suggests that compensation alone may not be sufficient to offset the detrimental effects of high job demands and burnout on nurses' intention to leave their jobs or the profession. Further research is warranted to explore potential moderators that may influence the relationship between job demands and turnover intention.

Keywords: burnout; job demands; job stress; pay level satisfaction; registered nurses; turnover intention

1. Introduction

Job demands for health have witnessed a significant increase worldwide due to the global phenomenon of rapidly ageing

populations and growing healthcare needs [1]. Hong Kong, like many other regions, grapples with the challenges posed by an ageing population, resulting in heightened job demands for nurses [2]. The shortage of nurses is a concern

shared by numerous countries, as a growing number of nurses approach retirement age or seek better career opportunities abroad. The aggregate number of registered practicing nurses and fresh nursing graduates grew by over 50%, rising from 43,698 in 2012 to 66,492 in 2022. However, it is projected that there will be shortages of 1383 and 1669 nurses in the years 2025 and 2030, respectively [2].

The healthcare industry is experiencing a shortage of manpower, coupled with escalating work demands, which has resulted in healthcare professionals working long hours and facing overwhelming workloads. Consequently, this has led to burnout and physical and mental exhaustion among healthcare professionals, ultimately increasing their intention to leave their positions [3]. The high turnover intention rate of registered nurses can have detrimental effects on the quality of patient care and the overall functioning of the healthcare system [1]. These repercussions include a lack of continuity of care for patients, increased workload in nurses who stayed, limitation of time nurses spending on each patient, increased healthcare cost, negative impact on employee morale and challenges in recruitment and staff orientation and training.

While there is a substantial body of literature on job demands, burnout and turnover intervention among healthcare practitioners, there is a notable gap in research focussing on the context of registered nurses within the Hong Kong public hospital setting. Previous studies, which are not limited to a specific geographical context, mainly focused on the intention to leave the profession. Little is known about the impact of job demands on the intention to leave the hospital. Existing research underexplored the moderating role of pay level satisfaction in the relationship between job demands, burnout and turnover intention. No cross-sectional study has been conducted to examine the direct and indirect effects of job demands on intention to leave hospitals and professions in registered nurses working in Hong Kong public hospitals. Hence, an empirical study is needed to explore the moderating effect of pay level satisfaction amongst registered nurses and provide valuable insights and potential solutions that can be adapted and implemented in healthcare systems facing similar workforce challenges. The findings of this study have the potential to inform policies and interventions aimed at improving nurse retention and enhancing the quality of patient care, not only in Hong Kong but also in other healthcare settings worldwide.

2. Background

2.1. Nexus of Job Demands, Burnout and Turnover Intention in Nursing. The nursing profession is grappling with a global challenge of elevated job demands, which have been identified as a significant factor contributing to burnout and turnover intention among employees. Job demands encompass the physical, mental and emotional efforts required to perform a job [4]. In the context of Hong Kong, registered nurses in public hospitals are particularly affected by high-demand workloads, as they are tasked with providing care for a large volume of patients [5]. Despite the international

recommendation of 9 nurses per 1000 people, Hong Kong falls slightly short with a ratio of 8.2 nurses per 1000 individuals [2, 6]. This shortfall contributes to excessive workloads, adherence to strict shift schedules, and the need for nurses to engage in training programs outside regular working hours [7, 8]. Factors such as long working hours, heavy workloads, inadequate staffing, and a lack of support for professional development have been cited as reasons for occupational turnover among nurses in Hong Kong [9].

The phenomenon of burnout and turnover intention is not unique to Hong Kong but is also observed in other regions. For instance, studies in China have shown a positive relationship between role demands and the intention to leave the hospital among frontline nurses [10], while South Korean nurses have demonstrated a positive association between burnout, emotional exhaustion and turnover intention [11]. Work–family conflict, where work responsibilities hinder the ability to meet family obligations, and family–work conflict, where family obligations impede work responsibilities, have both been positively associated with turnover intention [12–14]. Other studies have identified factors such as heavy workloads, relationships with physicians, full-time work schedules, burnout, and participation in hospital affairs as contributors to nurses' intention to leave the profession [15–17].

Burnout, a psychological response to chronic work stress, can mediate the relationship between job stress and turnover intention [18, 19]. It arises from continuous exposure to high patient volumes, complex medical cases, and emotionally demanding situations, leading to emotional exhaustion and detachment [20]. The mediating role of burnout on the impacts of job demands and family–work conflict on turnover intention has been demonstrated in various studies [21–24]. In addition to the direct impact of workload, nurses also face administrative tasks and interpersonal conflicts that can exacerbate job stress and reduce job satisfaction, potentially leading to turnover intention [25–27]. The implications of turnover intention are profound, affecting not only the healthcare system and continuity of patient care but also the well-being of nurses themselves [28]. Therefore, understanding and addressing the multifaceted nature of job demands is crucial for enhancing retention in the nursing profession, particularly in the high-pressure environment of Hong Kong's public hospitals.

2.2. Effect of Pay Levels Satisfaction on Nurses. Pay level satisfaction, which reflects an individual's subjective evaluation of their job compensation, has been recognised as a potential buffer against the negative effects of high job demands and burnout on nurses' turnover intentions [29, 30]. Studies across various regions have demonstrated the importance of pay satisfaction in the nursing profession. Wang et al. [31] found that pay satisfaction influenced geriatric nurses' turnover intentions both directly and indirectly. In China, Wang et al. [32] reported that wage satisfaction was a critical component of job satisfaction that negatively correlated with turnover intentions among

primary care providers. The finding of a negative relationship between pay satisfaction and turnover intention echoes the results reported by Wang et al. [31] in their investigation of geriatric nursing personnel in China. Internationally, Wardhani and Hariyati's [33] qualitative research in Indonesia revealed that pay growth played a significant role in nurse retention. High pay satisfaction may alleviate emotional exhaustion, a key aspect of burnout, thereby enhancing the ability to manage job demands and reducing the likelihood of turnover [34, 35]. Despite these insights, the moderating role of pay level satisfaction in the relationship between burnout and turnover intention remains under-explored. This study aims to fill this gap by examining whether pay level satisfaction can act as a counterbalance to the adverse effects of job demands and burnout on turnover intention, with a particular focus on the conditions faced by registered nurses in Hong Kong's public hospitals.

2.3. Theoretical Framework. The conceptual framework of this study (see Figure 1) was built upon the job demands-resources (JD-R) model proposed by Bakker and Demerouti [34]. This model suggests the interaction between job demands and job resources, where job demands are associated with negative effects on employee well-being, while job resources are associated with positive effects on employees [36]. Based on this model to explain the conceptual framework of this study, job demands refer to the physical and mental effort involved in work-related aspects. Specifically, job demands in our study include workload, job stress, work-family conflict, family-work conflict and conflict with nurses. These factors have been identified as significant dimensions within our research context and are crucial for understanding their impact on employee well-being and other outcome variables [4]. Burnout is the consequence of prolonged exposure to job demands and is the result of the imbalance between job demands and available resources [20]. The conceptual framework of this study proposes burnout as a mediator between job demands-related factors and turnover intention, while pay level satisfaction acts as a moderating factor. The study hypothesises that work overload, job stress, work-family conflict, family-work conflict and conflict with nurses will have direct positive effects on turnover intention and an indirect positive effect through burnout. Additionally, we postulated that pay level satisfaction will moderate the relationship between job demands-related factors, burnout, and organisational and professional turnover intention.

This study aimed to examine the conditional indirect effects of workload, job stress, work-family conflict, family-work conflict and conflict with nurses on organisational and professional turnover intention, with burnout serving as the mediator and to explore the moderating influence of pay level satisfaction in this relationship. This investigation was conducted using a two-step approach: (1) assessing whether the relationship between five job demands-related factors and organisational and professional turnover intention is mediated by burnout (i.e., mediation model) and (2) examining whether the strength of the mediated relationship is

moderated by pay level satisfaction (i.e., mediated moderation analysis). More specifically, it was hypothesised that the five components of job demands, namely, work overload, job stress, work-family conflict, family-work conflict and conflict with nurses, would have a positive direct effect on organisational and professional turnover intention. Additionally, it was hypothesised that burnout would mediate the relationship between the five job demands-related factors and turnover intention, exerting an indirect positive effect. It was asserted that pay level satisfaction would moderate the mediated relationship. Particularly, it was hypothesised that the direct and indirect relationship between the five job demands-related factors and organisational and professional turnover intention would be weaker when there was a high level of pay level satisfaction.

3. Methods

3.1. Design and Participants. The present study adopted a cross-sectional approach. Data were collected from registered nurses working at public hospitals in Hong Kong between October and December 2022. An online survey was randomly sent to the hospital executives or managers of the 43 public hospitals in Hong Kong. Ultimately, 13 public hospitals accepted the invitation. The purposes and the contents of the survey were demonstrated in the email and the first page of the online survey. The managers were asked to forward the online survey link to the nurses if they consented to be involved after reading the materials we sent. Participants' consent was confirmed by agreeing, completing and submitting the online survey. The online survey was made anonymous to preserve the confidentiality of the subjects' identities. Approval for the study was obtained from the Institutional Review Board of the authors' university (application number: HSEARS20220602001).

To be eligible for this study, participants should be (i) a registered nurse; (ii) currently working in a public hospital for at least 6 months; (iii) between the ages of 18 and 65; and (iv) able to read and write Chinese. Registered nurses who have worked in public hospitals for 6 months or more seem to be more familiar with the workings of the public healthcare system.

3.2. Measures. Job demands comprised five elements, including work overload, job stress, work-family conflict, family-work conflict and conflict with nurses. All items in the questionnaire were assessed by a seven-point response scale ranging from 1 (strongly disagree) to 7 (strongly agree). Higher scores indicated a higher level of job stress. Work overload was assessed by a five-item scale derived from Reilly's Role Overload Scale ($\alpha = 0.66-0.87$). The scale has been validated and widely applied [37]. Job stress is measured by four items adapted from the study of Graham et al. [38]. These items have been widely applied in assessing job stress amongst healthcare professionals [39, 40]. The Work-Family Conflict Scale (WAFCS), created by Haslam et al. [41], was the instrument used to gauge five work-to-family conflict items and five family-to-work conflict items.

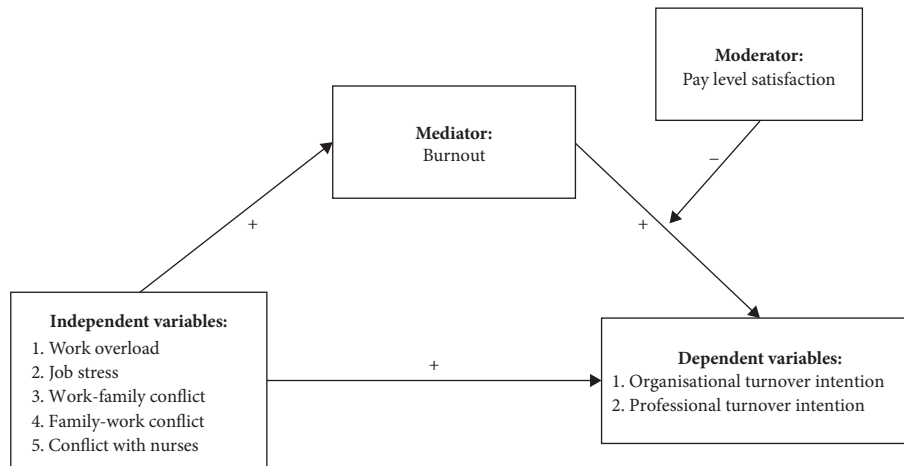

FIGURE 1: Study conceptual model.

The measure had a high internal consistency (work–family conflict: $\alpha = 0.84$) and (family–work conflict: $\alpha = 0.80$). Conflict with nurses was assessed by five items adapted from the Nursing Stress Scale developed by Gray-Toft and Anderson [42] ($\alpha = 0.7$).

Burnout was measured using six items adapted from the Maslach Burnout Inventory [43]. These six items were measured with a seven-point Likert scale which ranged from 1 (completely disagree) to 7 (completely agree). A higher rating indicated a higher level of burnout. This scale has been validated by Demerouti, Mostert and Bakker [44] and had a good internal consistency ($\alpha = 0.82$).

Pay level satisfaction was measured using five items adapted from Smith, Kendall, and Hulin [45] and Hackman and Oldham [46]. These five items were measured with a seven-point Likert scale which ranged from 1 (completely disagree) to 7 (completely agree). High scores indicated a high level of pay level satisfaction. The scale has a good internal consistency ($\alpha = 0.83$).

Turnover intention was assessed using two items, including “I do not want to continue working in this organisation” and another one was “I do not want to do this career.” These two items were adapted from the study of Yamaguchi et al. [47]. These two items were measured with a seven-point Likert scale which ranged from 1 (completely disagree) to 7 (completely agree). High scores indicated higher turnover intention.

A series of questions about demographic information such as age, gender, educational level, position and number of years since registration were included.

3.3. Data Analysis. The measurement model was verified through confirmatory factor analysis (CFA) using SPSS 28.0 and AMOS 28.0. CFA was conducted on the measurement model using SPSS 28.0 and AMOS 28.0 to assess its validity. Six goodness-of-fit indices were employed, namely, chi square to degree of freedom (χ^2/df), goodness-of-fit index (GFI), incremental fit index (IFI), comparative fit index (CFI), Tucker–Lewis Index (TLI), root mean square error of approximation (RMSEA), Parsimony goodness-of-fit index

(PGFI) and average variance extracted (AVE) [48]. The statistics analysis was performed using SPSS 28.0. The demographics of the participants were presented in descriptive analysis. The correlations between the participants’ demographics and study variables (job demands, burnout, pay level satisfaction and turnover intention) were examined by the bivariate Pearson correlation coefficient. The mediated moderation analyses were examined by PROCESS macro by Hayes [49]. The unstandardised coefficient beta and standard error for each path (between the study variables) were presented. This PROCESS macro tests the direct and indirect relationship between job demands and turnover intention and examines the mediator of burnout and the moderator of pay level satisfaction in this relationship. If significant moderating effects of pay level satisfaction were found, further moderating effects on different levels of pay satisfaction on turnover intention would be tested.

4. Results

4.1. Participant Characteristics. Table 1 demonstrates the description of participant characteristics. A total of 502 completed questionnaires were received from 13 hospitals. The study sample was comprised entirely of full-time registered nurses. Most of the participants were female (71.3%). The largest age group was those aged 30 to 40 (39.6%). 52.0% of the participants were single. 97.6% of the participants had a bachelor’s degree or above. The average year registered as a registered nurse was 13.1 (SD: 10.1) years. The average working hours per week was 46.5 (SD: 7.0) hours.

4.2. Results of Validity and Reliability of the Measurement Model. Table 2 shows the results of the validity and CFA of the measurement model. The values of AVE of all constructs ranged from 0.50 to 0.70 suggesting a good level of convergent validity. The values of χ^2/df , GFI, IFI, CFI, TLI, RMSEA and PGFI were 2.88 ($p < 0.001$), 0.92, 0.95, 0.95, 0.92, 0.06 and 0.70, respectively, satisfied with statistical standards [48]. Therefore, the measurement model presented satisfactory fit indices.

TABLE 1: Descriptive statistics of sample demographics and key variables ($N = 502$).

Nurse demographics		Frequency (%)	Mean (SD)	Range
Age	≤30	133 (26.5)	—	—
	>30–40	199 (39.6)	—	—
	>40–50	92 (18.3)	—	—
	>50	78 (15.5)	—	—
Gender	Male	144 (28.7)	—	—
	Female	358 (71.3)	—	—
Marital status	Single	261 (52.0)	—	—
	Married	234 (46.6)	—	—
	Divorced	7 (1.4)	—	—
Education	Diploma/higher diploma	12 (2.4)	—	—
	Bachelor's degree	201 (40.0)	—	—
	Master's degree	289 (57.6)	—	—
Years since registration		—	13.1 (10.1)	1.0–40.0
Years of working in this unit		—	7.8 (7.4)	0.4–35.0
Work departments	Cardiology	28 (5.6)	—	—
	Infectious disease department	11 (2.2)	—	—
	Intensive care unit	43 (8.6)	—	—
	Medical department	161 (32.1)	—	—
	Neurosurgery	2 (0.4)	—	—
	Obstetrics and gynaecology	53 (10.6)	—	—
	Oncology department	19 (3.8)	—	—
	Orthopaedics and traumatology	39 (7.8)	—	—
	Otolaryngology	11 (2.2)	—	—
	Paediatrics	54 (10.8)	—	—

Others	43 (8.6)	—	—	
Position	Registered nurse	335 (66.7)	—	—
	Advanced practice nurse/nursing officer	167 (33.3)	—	—
Average working hours per weeks (hours)		—	46.5 (7.0)	35–78
Need to raise children		174 (34.7)	—	—
No need to raise children		328 (65.3)	—	—
Need to take care of family members (in addition to children)		237 (47.2)	—	—
No need to take care of family members (in addition to children)		265 (52.8)	—	—
Living with family		453 (90.2)	—	—
Not living with family		49 (9.8)	—	—

Abbreviation: SD, standard deviation.

4.3. Correlations of Variables. The Spearman correlation coefficient was used since the data set did not exhibit a normal distribution according to the Shapiro–Wilk test. Table 3 presents the Spearman correlation between the variances. Work overload, job stress, work–family conflict, conflict with nurses and burnout were positively correlated with organisational and professional turnover intention. Pay level satisfaction was negatively correlated with organisational and professional turnover intention. There was no significant association found between nurses' experiences of family-interfering-with-work conflict and their reported plans to leave their current job or the nursing profession. Work overload, job stress, work–family conflict, family–work conflict and conflict with nurses were positively correlated with burnout. Work overload, job stress, work–family conflict, conflict with nurses and burnout were negatively correlated with pay level satisfaction and family–work conflict had no significant correlation with pay level satisfaction.

4.4. Mediated Moderation Analysis. Work overload, job stress, work–family conflict, family–work conflict and conflict with other nurses has a positive statistically significant impact on burnout (work overload: $B = 0.590$, $p < 0.001$; job stress: $B = 0.817$, $p < 0.001$; work–family conflict: $B = 0.581$, $p < 0.001$, family–work conflict: $B = 0.256$, $p < 0.001$; conflict with nurses: $B = 0.480$, $p < 0.001$) (Table 4).

Table 5 demonstrates the results of mediated moderation analysis of burnout and pay level satisfaction on the relationship between job demands-related factors and organisational turnover intention. Statistically significant associations were found between work overload ($B = 0.153$, $p < 0.028$), job stress ($B = 0.287$, $p < 0.014$) and conflict with other nurses ($B = 0.280$, $p < 0.001$) with organisational turnover intention. Additionally, family–work conflict ($B = 0.574$, $p < 0.001$) was positively associated with organisational turnover intention, while work–family conflict did not demonstrate a significant effect. Burnout was

** $p < 0.001$, * $p < 0.05$.

found to have statistically significant mediating effects in all five relationships ($p < 0.001$). Pay level satisfaction had a statistically significant impact on organisational turnover intention ($p < 0.001$). However, pay level satisfaction did not demonstrate a significant moderating effect on the mediated relationship.

The results of the mediated moderation analysis, examining the influence of pay level satisfaction as a moderator on the relationship between job demands-related factors, burnout and professional turnover intention are demonstrated in Table 5. Work overload ($B = 0.253$, $p < 0.002$) and conflict with other nurses ($B = 0.351$, $p < 0.001$) showed statistically significant associations with professional turnover intention, while job stress, work-family conflict and family-work conflict did not exhibit a significant effect. Burnout was found to have statistically significant mediating effects in all five relationships ($p < 0.001$). Furthermore, pay level satisfaction showed a statistically significant impact on organisational turnover intention ($p < 0.05$). However, pay level satisfaction did not demonstrate a significant moderating effect on the mediated relationship.

Table 6 shows the results of the direct and conditional indirect effects of job demands-related factors on organisational turnover intention with the mediator of burnout and the moderator of pay level satisfaction. For the indirect effects of work overload, the indirect effect in the presence of the moderator, pay level satisfaction, at mean level, one standard deviation below mean and above mean were 0.333, 0.304 and 0.362, respectively, and per the bootstrap, that is within the confidence interval at a $p < 0.05$. Similarly, for job stress, the bootstrap analysis revealed significant effects at mean level, one standard deviation below mean, and one standard deviation above mean of pay level satisfaction (0.419, 0.395 and 0.442, respectively, $p < 0.05$). Work-family conflict also showed significant indirect effects on organisational turnover intention at the different levels of pay level satisfaction (0.333, 0.311 and 0.356, respectively, $p < 0.05$). The indirect effects of family-work conflict on organisational turnover intention were significant at mean level, one standard deviation below mean and one standard deviation above mean of pay level satisfaction (0.172, 0.158 and 0.187, respectively, $p < 0.05$). Conflict with other nurses had significant indirect effects on organisational turnover intention across the different levels of pay level satisfaction (0.228, 0.208 and 0.248, respectively, $p < 0.05$). The findings suggest indirect effect of work overload, job stress, work-family

conflict, family-work conflict and conflict with other nurses on organisational turnover intention through burnout is stronger or more pronounced when registered nurses have a higher level of satisfaction with their pay levels. The index of mediated moderation is not significant, indicating that the indirect effect is not moderated by pay level satisfaction.

Table 6 presents the results of direct and conditional indirect effects of job demands-related factors on professional turnover intention. Burnout serves as the mediator, and pay level satisfaction acts as the moderator. Considering the indirect effects of different factors on professional turnover intention, the bootstrap analysis shows that work overload has a significant indirect effect in the presence of pay level satisfaction at mean level, one standard deviation below mean and one standard deviation above mean (0.293, 0.277 and 0.309, respectively, $p < 0.05$). Similarly, job stress has a significant indirect effect on professional turnover intention across the different levels of pay level satisfaction (0.434, 0.429 and 0.439, respectively, $p < 0.05$). Work-family conflict demonstrates a significant indirect effect on professional turnover intention at mean level, one standard deviation below mean and one standard deviation above mean of pay level satisfaction (0.308, 0.302 and 0.315, respectively, $p < 0.05$). Likewise, family-work conflict shows a significant indirect effect on professional turnover intention across the different levels of pay level satisfaction (0.165, 0.159 and 0.172, respectively, $p < 0.05$). Moreover, conflict with other nurses has a significant indirect effect on professional turnover intention in the presence of different levels of pay level satisfaction (0.199, 0.192 and 0.206, respectively, $p < 0.05$). The findings suggest that indirect effect of work overload, job stress, work-family conflict, family-work conflict and conflict with other nurses on professional turnover intention through burnout is stronger or more pronounced when registered nurses have a higher level of satisfaction with their pay levels. The index of mediated moderation is not significant, indicating that the indirect effect is not moderated by pay level satisfaction.

5. Discussion

The present study's exploration of the mediating role of burnout in the relationship between work overload, job stress, work-family conflict, family-work conflict, conflict with nurses, and organisational and professional turnover intentions among registered nurses in Hong Kong's public

TABLE 6: Direct and conditional indirect effects of work overload, job stress, work–family conflict, family–work conflict and conflict with other nurses on the organisational and professional turnover intention with the mediator of burnout and moderator of pay level satisfaction.

hospitals has yielded significant insights. We can gain a better understanding of the complex interplay between job demands-related factors and burnout and turnover intentions, thereby enhancing our knowledge of the challenges faced by nurses and the potential strategies for improving retention in the nursing profession by delving deeper into the results.

Our findings highlight the mediating role of burnout in the relationship between the five factors of job demands and organisational and professional turnover intentions. These are consistent with previous studies that determined burnout as the response to job demand, job stress, work overload, work–family conflict, family–work conflict and poor relationship with colleagues [18, 50–52]. Moreover, our findings confirm that the intention to leave both the current job and the nursing profession can be attributed to burnout among nurses [15, 22].

The study revealed significant effects of work overload, job stress and conflicts with nurses on organisational turnover intention. Work overload and conflicts with nurses were found to have significant effects on professional turnover intention. Remarkably, conflict with other nurses emerged as the primary and most prominent correlate, influencing both organisational and professional turnover intentions. These findings match the earlier studies that workloads are the driving factors of nurses' organisational and professional turnover intentions [12, 53]; nurses' job stress leads to the intention to leave the hospitals [54, 55]; conflict with colleagues increases the intention to leave the hospitals and occupation [54, 56]. Reinhardt et al. [57] found that better relationships with colleagues improved retention amongst registered nurses in the United States. These results corroborate the established understanding that burnout acts as a critical mediator between job demands-related factors and organisational as well as professional turnover intentions, aligning with the theoretical framework posited by the JD-R model [34].

Contrary to previous studies [29, 58], pay level satisfaction did not moderate the relationships between job demands-related factors, burnout, and organisational and professional turnover intentions. These unexpected results may be due to uniform pay structure, perceived fairness of pay systems and policies, nonfinancial factors and cultural norms and values. A standardised salary scale for registered nurses may limit variability in pay levels across the labour [59]. There may not be enough variation in pay level satisfaction to detect a significant moderating effect when most registered nurses receive similar pay under this pay system. A transparent pay system may lead to perceptions of fairness and pay equity [59–61]. This may diminish the moderating effect of pay level satisfaction on the job demands–turnover intention relationship. Further, nonfinancial factors, such as job autonomy, supportive work environments or professional development opportunities, which may be more influential in determining nurses' turnover intention among nurses, might overshadow the impact of pay level satisfaction as a moderator [62]. Cultural norms and values, such as a strong work ethic, could be a prioritising factor in determining the intention to leave [63, 64].

According to the JD-R model, pay level satisfaction is expected to buffer the negative effects of job demands on turnover intention [65]. However, if the employee perceived their job demands as compensated by adequate pay, the moderating effect of pay level satisfaction might be diminished. In this case, the nurses may perceive other job resources, such as social support and career development opportunities, as compensation for high job demands [66]. For instance, the meta-analysis of Kim and Kim [11] showed that factors other than salary, including interpersonal relationships, social support, organisational justice and person–organisational fit, were significantly and negatively associated with turnover intention amongst nurses in South Korea. As a result, the moderating effect of pay level satisfaction may be attenuated. The specific reasons for the lack of moderation effect of pay level satisfaction in the given context would require empirical investigation and further research to provide more concrete explanations.

It is somewhat surprising that family–work conflict had negative impacts on organisational and professional turnover intention, while work–family conflict had no significant association with organisational and professional turnover intention. Extensive research has shown that work–family conflict and family–work conflict predict the nurses' intention to leave the hospitals and profession [47, 67, 68]. This finding may reflect a complex interplay of personal and professional values, cultural expectations and life-stage considerations that influence turnover decisions. It is possible that for the younger, predominantly single nurses in this study, professional aspirations and career progression may take precedence over family obligations, thus reducing the impact of family–work conflict on their turnover intentions. Our demographic analysis revealed that younger caregivers in our study (under 30 years old) were more likely to be single and without dependent children. This suggests that family obligations may be less important for this group than for older, married/partnered individuals. Further qualitative research could provide richer insights into these personal and cultural factors that shape nurses' work-life integration and turnover behaviour.

Regarding practical implications, this study highlights the significance of addressing conflict with other nurses. Conflict with colleagues emerged as the primary and most prominent factor in organisational and professional turnover intention. Healthcare organisations should prioritise interventions aimed at promoting effective communication, collaboration and conflict resolution among nursing staff. Creating a positive work environment that fosters teamwork and mutual respect can help mitigate conflicts and reduce turnover intentions. Furthermore, the study underscores the importance of managing work overload. Healthcare organisations should explore strategies to effectively manage workloads, such as workload redistribution, task prioritisation and resource allocation. By addressing work overload, healthcare organisations can alleviate the burden on nurses and enhance job satisfaction, ultimately reducing turnover intentions. Additionally, the findings emphasise the role of burnout as a mediating factor. The study identified statistically significant mediating effects of burnout in all five of

the relationship dynamics that were explored. To mitigate burnout among nursing staff, healthcare organisations should prioritise interventions aimed at preventing and managing burnout. This may include providing resources for stress reduction, promoting self-care practices and offering emotional support to nurses. By addressing burnout, healthcare organisations can improve job satisfaction and reduce turnover intentions.

This research further accentuates how family-interfering-with-work conflict can shape nurses' considerations of quitting their organisation. Healthcare organisations should recognise and address the challenges faced by nurses in balancing their work and family responsibilities. Implementing family-friendly policies, flexible work arrangements and support systems for childcare or eldercare can help reduce family-work conflict and mitigate turnover intentions among nursing staff. However, it is important to note that pay level satisfaction did not demonstrate a significant moderating effect on the relationship between job demands-related factors and burnout and turnover intentions. Therefore, healthcare organisations should adopt a comprehensive approach that considers various factors, including work environment, workload management, interpersonal relationships and support systems, in addition to fair compensation. This multifaceted approach should go beyond salary adjustments and encompass strategies such as mentorship programs, career development pathways and wellness initiatives that target burnout prevention. By considering these multiple factors, organisations can create an environment that supports nurses' well-being and reduces the likelihood of turnover. Taking a holistic approach to nurse retention will foster a positive work environment and promote the long-term satisfaction and commitment of registered nurses in the healthcare sector.

5.1. Limitations and Future Research Directions. This study contains several limitations. First, the cross-sectional design limited the ability to establish causal relationships between study variables. To provide more robust evidence of causality by capturing changes in variables over time, future research is encouraged to employ longitudinal designs. This approach would enable a deeper understanding of the temporal dynamics and causal pathways involved. Second, it is important to note that the participants in this study consisted of registered nurses from public hospitals in Hong Kong. Thus, caution should be exercised when generalising the findings to other contexts, such as private hospitals or healthcare systems in different countries. Further investigations should encompass diverse healthcare settings and populations to enhance the generalisability and external validity of the results. Third, the present study did not include certain variables that may exert influence on the examined relationships. Variables such as organisational culture, social support, and job autonomy are recognised as potential factors in the complex interplay between work-related elements and burnout and turnover intentions. Incorporating these additional variables in future research endeavours

would yield a more comprehensive understanding of the phenomenon and enable the identification of additional factors that contribute to the outcomes of interest.

To advance the current knowledge in this field, future research should explore multiple avenues. First, employing longitudinal designs would aid in understanding the long-term effects of work-related factors on burnout and turnover intentions, as well as uncovering causal mechanisms. Second, including a wider range of variables such as organisational culture, social support, job autonomy, and other relevant psychosocial factors would provide a more comprehensive understanding of the complexities involved. Additionally, expanding the investigation to encompass different healthcare contexts, both nationally and internationally, would enhance the applicability and external validity of the findings. Moreover, qualitative research methods, such as interviews or focus groups, could be used to gain in-depth insights into nurses' experiences and perspectives concerning work-related factors and burnout and turnover intentions. These qualitative approaches would complement the quantitative findings and offer a deeper understanding of the underlying mechanisms.

6. Conclusions

The study was to determine the mediating effect of burnout and the moderating effect of pay level satisfaction in the indirect effect of job demands on turnover intention. The findings highlight the detrimental impact of work-related factors, such as work overload, job stress and conflict with other nurses, on nurse burnout and turnover intentions. While pay level satisfaction was negatively correlated to turnover intention, the lack of a significant moderating effect suggests that addressing burnout and turnover intentions requires a comprehensive approach that goes beyond focussing solely on pay satisfaction. Public hospitals should consider implementing strategies that tackle multiple factors contributing to burnout. The findings emphasise the need for healthcare organisations and policymakers to prioritise interventions aimed at reducing work-related stress and burnout among registered nurses in public hospitals in Hong Kong. By addressing these factors and fostering a supportive work environment, healthcare organisations can promote nurse well-being, mitigate turnover intentions and contribute to the overall quality of patient care.

Object. To explore nurses' experiences and perceptions of implementing pharmaceutical technical assistants on hospital wards for medication dispensation. The study focuses on implementation, role development, and impact on safety and quality of care, identifying critical success factors and improvement opportunities. **Methods.** In a qualitative descriptive study, between December 2022 and March 2023, 16 semistructured interviews were carried out with a stratified purposive sample of nurses across internal, surgical, and geriatric wards. The inclusion criteria required a minimum of six months of work experience and experience working both day and night shifts. Inductive thematic analysis was performed in NVivo 1.6.1. **Results.** Semistructured interviews revealed three main themes: (1) patient safety and quality of care, (2) organization of care, and (3) role development and collaboration. The implementation of pharmaceutical technical assistants on nursing wards was perceived to reduce the risk of medication errors without compromising care quality, allowing nurses to spend more time on direct patient care. Clear communication procedures were vital for successful implementation, highlighting the need for collaboration and information exchange between pharmaceutical technical assistants and nurses. Continuity in assigning pharmaceutical technical assistants was highlighted as crucial to improve medication safety and quality of care. This is considered an important aspect to ensure a smooth and optimal cooperation between nurses and pharmaceutical technical assistants. Nurses expressed that working with pharmaceutical technical assistants challenged their supervisory role and teamwork dynamics. **Conclusions.** Nurses confirmed the added value of pharmaceutical technical assistants in medication management. Critical factors included dedicated assignments to hospital wards, clear roles, and mutual expectations in collaboration with ward nurses.

1. Introduction

The medication process on hospital wards is a routine but complex activity, involving multiple steps (prescription, dispensation, preparation, double-checking, administration,

and evaluation) and various healthcare professionals. However, a critical workforce crisis is growing, with a projected global shortage of 7.2 million healthcare professionals expected to increase to 12.9 million by 2030, including a shortfall of 5.9 million nurses [1, 2]. Nurses have a unique

role in medication administration [3, 4]. In the medication process, there are specific actions for nurses (such as administering), but there is also overlap in actions that can be performed by other healthcare professionals (e.g., dispensing and preparing).

At the dispensing and administration stage, errors are common (32–38% of all medication errors that harm patients) [5]. Medication errors are defined as preventable events that (have the potential to) harm the patient [6]. Medication errors can be caused by structural factors in nursing practice, including high workload, stressful environments, distractions, multitasking, and interruptions [7–10]. Sheik et al. [11] found disruptions during patient care contribute to half of hospital medication errors in patient files.

Studies suggest that pharmaceutical technical assistants (PTA) can contribute to hospital wards to a substantial improvement of medication dispensation [12–15]. Beyond dispensing, PTAs may perform other roles in a hospital. A literature review suggests that through the use of PTAs within medication reconciliation, hospitals experienced cost savings and other healthcare professionals saved time for other patient care activities, as well as increased trust in the accuracy of medication history [16].

A general hospital in Belgium, Vitaz, implemented PTAs to achieve high-quality medication service and allow nurses, physicians, and pharmacists to practice at the highest level of their licence. Between January 2021 and June 2022, ten PTAs were assigned to six hospital wards from Monday through Friday. Each PTA had two hours of daily medication dispensing and making stock corrections for the coming 24 hours. Nurses remained responsible for medication control and administration to patients [17].

Implementing PTAs on hospital wards can improve medication dispensation. Studies reveal that nurses, involved in direct patient care, experience more interruptions than PTAs. This allows PTAs to focus on dispensing medication [15, 18]. The main reason for implementing PTAs on hospital wards is to improve the job characteristics of nurses by reducing their workload and releasing additional time for direct patient care [15]. The integration of PTAs changes the organizational structure of a hospital ward, which can contribute to avoiding medication errors. Furthermore, this integration may lead to job enrichment and job satisfaction of the hospital PTAs [19, 20].

The PTA in Belgium, recognized since 1997, is a paramedic professional who is responsible for the dispensation of medication under the supervision of a pharmacist. Education, with at least 300 hours of practical internship in a pharmacy, is scaled to level 4—technical secondary education in the European qualification framework and the International Standard Classification of Education [21, 22]. A Belgian PTA is certified to perform acts, such as receiving and registering prescriptions, medication delivery, informing patients about adequate and safe use, making preparations, and training PTAs [23].

To evaluate and improve the role and implementation of PTAs on the hospital ward, nurses are key stakeholders. Nurses experience changes in organizational structure on

a daily basis, can detect potential risks, and suggest improvements. This study aimed to explore nurses' experiences and perceptions of the implementation of PTAs on hospital wards to support the medication dispensation process, role development, and impact on safety and quality of care to determine critical success factors and opportunities for quality improvement.

2. Methods

2.1. Study Design, Setting, and Period. A qualitative study with individual semistructured interviews took place on hospital wards (December 2022–March 2023). These wards had PTAs assigned during this study or between January 2021 and June 2022.

2.2. Participants and Sample Procedure. In this study, 16 semistructured interviews were carried out with a stratified purposive sample of nurses across internal, surgical, and geriatric wards. The inclusion criteria required a minimum of six months of work experience and experience working both day and night shifts. Participants were informed about the study through written and oral communication, including e-mail, telephone, and face-to-face interactions. Data saturation was assessed through consensus among the project group members (MDG, BS, TD, RH, and ND) and was achieved after conducting 16 interviews.

2.3. Data Collection. The interview guide was informed by a review of the literature on the roles of PTAs on hospital wards. Open-ended questions aimed for participants to freely express their personal experiences on organization, work environment, collaboration, role development, criteria, and potential benefits of the implementations of PTAs on hospital wards. The interview guide was discussed and refined at regular project group meetings. All interviews were conducted by MDG or VVR, audio recorded, pseudonymized, and transcribed verbatim. The interviews were held in a separate and quiet room. The accuracy of the transcripts was reviewed by proofreading by the two researchers. To describe the population, the following demographic data were collected: sex, age, education level, years of experience, and current job time.

2.4. Data Analysis. Inductive thematic analysis was conducted in NVivo 1.6.1 to uncover emerging patterns and (sub)themes from the data. Two researchers (MDG and VVR) independently coded the data to enhance the credibility of the findings. After analysing the first four interviews, the researchers held a cross-check meeting to ensure consistency in coding strategies and refine approaches, such as clustering codes and formulating (sub)themes. This iterative process continued throughout data collection, with a final meeting held when both researchers independently reached data saturation, indicating that no new themes were emerging. To mitigate potential biases in data gathering, analysis, and reporting, the preliminary analysis findings

were presented to the project group for further discussion. Finally, to ensure a thorough exploration of the identified themes and subthemes, all project group members engaged in comprehensive discussions until consensus on the final thematic framework was achieved.

2.5. Credibility and Trustworthiness. Data triangulation involved a meticulous cross-validation process. To allow critical and sense-making discussion of data interpretations, regular cross-check meetings between the two researchers were held. In addition, discussions within the project group provided a valuable collaborative perspective that served to validate the findings and mitigate potential bias. After the analysis, the findings were presented to the participants using a thematic presentation of the themes. The participants discussed these findings to reduce the risk of superficial or false interpretation and confirmed that the quality of data analysis was rigorous and reliable. This interactive dialogue provided a deeper exploration of the participants' experiences and insights, reducing the risk of superficial or false interpretations, and ensured that the data analysis was embedded in the participants' experiences.

2.6. Ethical Considerations. The study adhered to the Declaration of Helsinki and received approval from the Ethics Committee of Vitz (registration number EC/22054) [24]. The study was reported according to the Consolidated Criteria for Reporting Qualitative Studies (COREQ) checklist for qualitative research [25].

3. Results

Seven head nurses and nine nurses were interviewed for a total of 347 minutes, with a mean duration of 21.7 minutes (range 18–29) per interview. The majority of the interviewees were females ($n = 11$, 69%), with a mean age of 40.8 years, and 13 (81%) participants had more than five years of work experience (Table 1).

Nurses had a positive perception of the implementation of PTAs to support the process of medication management on hospital wards. All participants endorsed the content, formulation of themes, and deeper insights in the thematic presentation and discussion of the themes. Substantial changes were not required after this presentation. The analysis identified three main themes: (1) organization of medication management by PTAs, (2) patient safety and quality of care, and (3) role development and collaboration (Figure 1). These main themes are divided into several subthemes and described hereafter.

3.1. Organization of Medication Management by PTAs. In terms of the organization of medication management by PTAs on the hospital ward, five subthemes were described by nurses' experiences: (1) work instructions, (2) moment and place medication preparation, (3) continuity of the assignment of PTAs, (4) management medication stock, and (5) communication.

TABLE 1: Participants' characteristics.

Characteristics of nurses ($n = 16$)	n (%) / Mean (range)
Gender	
Male	5 (31)
Female	11 (69)
Age, mean (range), y	40.8 (24–58)
Educational level

EQF and ISCED-P* level 6	5 (31)
Work experience	
6 months < 5 y	3 (19)
5–10 y	2 (12)
>10 y	11 (69)

*EQF: European Qualification Framework and ISCED: International Standard Classification of Education 2011.

3.1.1. Work Instructions. Nurses mentioned misunderstandings of PTAs' responsibilities due to unclear insight of PTAs' time on the ward. Nurses emphasized the need for clear and well-defined work instructions for optimal medication dispensation. These work instructions are fundamental for all healthcare professionals to understand and set expectations for PTAs on the hospital ward.

Nurse 5: "Sometimes there are misunderstandings. Like the other day, our PTA said they are not allowed to take from the home medication to prepare. But those are things we as nurses don't know, unless we verify it with our pharmacist."

Nurse 13: "They actually prepare all the medication according to the medication program. I don't think there are really concrete agreements."

3.1.2. Moment and Place Medication Dispensation. The timing and location of the medication dispensation by PTAs emerged as a notable consideration in the organization of the medication dispensation on the hospital ward. At the initial start of the implementation of PTAs, they performed their tasks on the hospital ward in the afternoon. Later, to be able to provide more hospital wards with this pharmacy service, the organization made operational adjustments by sending PTAs to some hospital wards in the morning.

Nurse 3: "It's always busy in the same rooms. That place is too small and everything comes together. The telemetries go off constantly, nurses come there to wash their hands, the shift change, etc. There should be walls, a really separate room, that would make a difference. In fact, that's how it should be to prepare medication in completely enclosed rooms."

Participants indicated that the moment of medication dispensation by the PTAs influences the workload of nurses and their ability to provide direct patient care. When PTAs dispense the medication for the following day in the morning, there is a higher risk of medication changes than when this is done in the afternoon, especially after the

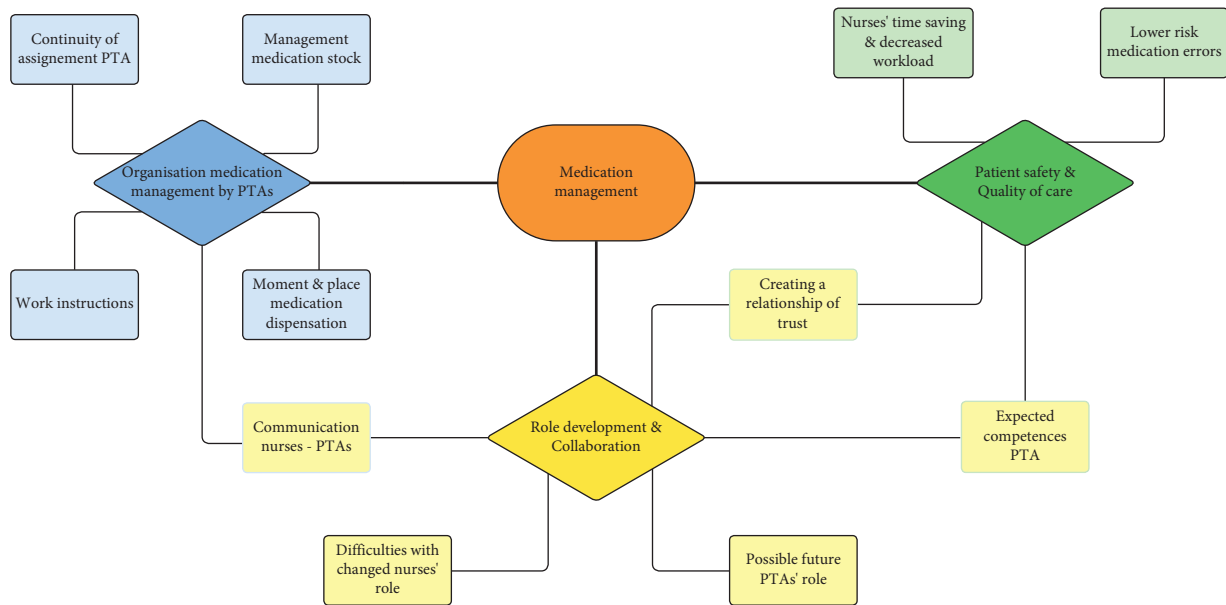

FIGURE 1: Main themes and interconnected subthemes of nurses' perception of the implementation of PTAs to support the medication management process on hospital wards.

doctor's round, when medication use is evaluated. Nurses mentioned that greater awareness of the moment of medication dispensation by PTAs is critical to prevent night nurses from spending, again, additional time supplementing and reviewing the medication dispensed by PTAs. Careful consideration of the optimal time for medication preparation by PTAs is crucial to maintain quality of care, minimize interruptions, and reduce the risk of medication discrepancies.

Nurse 15: "At this point they come to prepare in the morning, if an emergency admission occurred the day before, you have not received medication yet, because it does not arrive until the afternoon. If the doctor prescribes something in the morning, they have not seen it, because they have been there before the doctor has made all the adjustments. . . Things are really not going well on the ward at the moment."

To achieve high-quality medication dispensation, participants mentioned the importance of an enclosed, quiet medication room on the hospital ward. These environmental conditions were seen as essential elements to concentrate and perform their tasks with precision. The quiet condition not only allowed the PTAs to focus on their task but also served as a protective barrier against distractions or interruptions, which can potentially contribute to medication errors.

3.1.3. Continuity of Assignment PTAs. The continuity of assignment in terms of daily allocation of PTAs and in terms of the medication management process recurred frequently throughout the interviews. PTAs can be allocated to different wards every day; however, all participants perceived that the structural allocation of PTAs to the same hospital wards could have many advantages. The potential benefit of this

approach is a closer and more collaborative relationship, effectively forming a unified team that aims to build trust between nurses and assigned PTAs. In addition, nurses highlighted that when PTAs are consistently assigned to the same hospital wards, they have the opportunity to improve their clinical reasoning skills, which may contribute to the quality of care delivered.

Nurse 3: "The biggest frustration of nurses: we are here 24/7 and every discipline that comes to support us is limited."

Different opinions arise on the availability of PTAs during the week or weekends. Some express frustration over the fact that PTAs are only available on weekdays when nursing care is a requirement 24/7. On the contrary, other participants are of the opinion that PTA support might not be as essential during weekends and holidays, noting a perceived decrease in workload. Participants indicated that these varying perspectives are often linked to the unique needs of individual hospital wards. Surgical wards, for example, tend to experience a higher patient turnover during the week compared to weekends and holidays, leading to a lower workload on weekends and holidays. Geriatric wards often experience continuous bed occupancy, maintaining a consistent workload throughout the week, unaffected by specific days.

Nurse 5: "Especially during the week, because on the weekends you have fewer patients, normally, and on the other hand, speaking for myself, you are pulling the strings yourself again."

Nurse 11: "It would be easier if you have someone specific, or a couple of pharmacy assistants, who alternate specific on your hospital ward. Because you don't see someone else every day, but you can build a relationship of trust."

3.1.4. Management Medication Stock. Most nurses agreed that the introduction of PTAs improved the accuracy and efficiency of medication stock management on the hospital ward. PTAs overseeing this aspect reduced nursing time spent on frequent pharmacy calls for dispensing, restocking, or addressing missing medications. However, it is important to note that not all nurses shared the same perspective. Some nurses believed that PTAs could improve their role by ensuring that the necessary medications for the next 24 hours are in stock on the ward. This perspective emphasizes the ongoing pursuit to refine the balance between medication stock management and anticipating the specific needs of the ward.

Nurse 3: “Make sure that your antibiotics or important medications are in stock for the first 48 hours, so that the next shift does not have to call ‘we’re on our last medication’.”

Nurse 16: “If they see that we have shortages in the closet, they pass it on to their colleagues and then that medication comes faster to the hospital ward. I have to call a lot less to the pharmacy to tell them there is a shortage of medication stock. That’s something I really notice.”

3.1.5. Communication between Nurses and PTAs. The subtheme “communication” not only plays a vital role in organizing medication management, but also has far-reaching implications for role development and collaboration. All participants mentioned that effective communication between nurses and PTAs is essential to ensure patient safety and effective implementation.

To improve adequate communication between PTAs and nursing staff and mitigate the risk of medication errors, the hospital introduced a communication tool called “medication-attention cards.” These cards were designed to be placed within patient medication trays, highlighting crucial information, such as missing doses (ordered by hospital pharmacy), multidose medications, or medications on a medication strip. However, most of the participants expressed doubts about the effectiveness of this approach. There was often uncertainty about interpreting these medication-attention cards, and their inclusion was seen to potentially clutter and confuse the medication tray. On the contrary, nurses noted the critical need for a simplified and efficient method to facilitate the exchange of medication information between PTAs and nursing staff.

Nurse 2: “There are often little cards inside, pink, blue, and yellow. . . That means something like multidose medication, like insulin. But we don’t really know exactly what those cards mean, what medication they are about.”

Nurse 15: “That pink one, that is for the ordered medication. If the pharmacy has already seen it but does not have it, they place that to draw attention to the night nurse, ‘here should be an additional pill’.”

3.2. Role Development and Collaboration. This theme is divided into five subthemes: difficulties with changed nurses’ role, team, communication, competencies of PTAs, and possible future PTAs’ role.

3.2.1. Difficulties with Changed Nurse’s Role. The implementation of PTAs into the medication dispensation process represents a substantial task shift and introduces role differentiation between PTAs and nurses. This transition led to a decrease in overall workload; an improvement acknowledged by all participants. However, an interesting and nuanced perspective emerged among some participants who found it challenging to completely disengage from medication dispensation responsibilities, particularly during the night shift. These participants mentioned a sense of responsibility to ensure the accuracy of medication dispensation for their colleagues who worked the following day. This feeling of accountability extended to maintaining a clear overview of their patients’ medication regimens, recognizing their critical role in intercepting potential errors in medication prescriptions, especially concerning oral and subcutaneous anticoagulant, double antibiotics, etc. In addressing these concerns, many participants indicated a practice they adopted during the night shift: a “quick check” of medications dispensed by PTAs. This creates an additional third check before the medication reaches the patient. Although this is an additional and unattended step, this improvised verification process was perceived to provide an additional layer of medication safety.

Nurse 12: “Like today, the morning shift has already prepared half of the medication and the evening shift is going to complete the other half, so the night shift can be reassured: they only have to perform a last check and prepare the medication for new admissions.”

Exactly for that reason, several participants mentioned their willingness and even satisfaction with the responsibility of dispensing medication on weekend and holiday nights. This allowed them to periodically review and maintain a clear medication overview, minimizing the potential risk of losing track of medication details. In essence, it provided a resource for nurses to address proactively any discrepancies or potential errors in medication prescriptions, reaffirming their commitment to patient safety. Interestingly, there are also certain hospital wards where day nurses now undertake the task of medication dispensation for the following day when there are no PTAs available to support them.

Nurse 15: “We are much less aware of the medications the patients are taking. As a night nurse you sometimes see things like ‘he is taking that and that together’ or ‘he complains about that, but he gets this and this’. we miss that a bit by not preparing it anymore. Of course, at busy times we are happy that it is already done, but sometimes

we miss not having a good overview of patients' medication. Some things are important to keep in mind."

3.2.2. Creating a Relationship of Trust. The participants mentioned the importance of assigning PTAs to the same hospital wards as an important factor for closer collaboration and integration into the healthcare team. The participants perceived that when the same PTAs worked on their hospital ward, they could learn to know each other and begin building a relationship of trust. However, all participants indicate that there is pleasant contact with the PTAs, and they do not have the feeling to be one team. Although PTAs have a uniform way of working on all the different hospital wards, participants appreciate it when PTAs make small adjustments in their working methods to accommodate the habits of the ward. For example, a hospital ward has the habit of using medication jars with different colours for each moment of the day. On this ward, PTAs and nurses agreed to prepare the medication for the next day in coloured jars, provided that the nurses already had the jars ready to go.

Nurse 1: "They should be part of your team. I know we will not be the only team. I think they will probably work on two or three hospital wards. It is a matter of creating that bond of trust and that includes communication. That is just the way it is, and that trust needs to be created. That is something that needs to grow, you cannot force it."

Nurse 14: "Unfortunately, it doesn't seem like that, it seems a bit separate. But actually, I think that, if you work with permanent people, they will really become a part of the team."

3.2.3. Communication between Nurses and PTAs. All participants perceived that effective communication among various healthcare professionals is the key to successful working collaboration. They recognized four important aspects of communication: content, participants, time, and moment. The presence of a clear and standardized procedure for each of these aspects is important for all participants. Most of the participants expressed their desire for regular consultation moments, which they perceived as opportunities to exchange feedback in both ways. They recognized the importance of these moments in facilitating an open and constructive dialogue, enabling each professional to share insights, perspectives, and concerns.

Nurse 3: "Maybe ask for feedback: 'was everything clear?', 'I prepared the medication yesterday, do you have comments for me?' People rarely ask for feedback themselves; it can work well on both sides, I think."

3.2.4. Expected Competencies of PTAs. Comprehensive awareness of the competencies and authorizations of the PTAs is lacking among nurses. They described that this lack of clarity has contributed to their hesitancy to seek guidance

from PTAs about the medication of their patients. Nurses shared a collective expectation for more clinical reasoning skills among PTAs and seeing them as integral members of the healthcare team. Therefore, participants emphasized the need for clarity on the core competencies and cognitive processes expected from PTAs. This clarity, they believed, should be integrated into supplementary education, assessment, and practical training for PTAs.

Nurse 2: "I don't actually know what kind of training they have had. What do they know? Can we ask them questions about medication or do we really have to call the pharmacy for that?"

Nurse 3: "Basic training, clinical reasoning. A crash course: always look at the context of your patient, if in doubt, consult with the nurse who probably knows the patient better."

3.2.5. Possible Future Roles of PTAs. The lack of comprehensive knowledge on the competencies and authorizations of the PTAs was also reflected when participants were asked about the potential to expand the roles and responsibilities of the PTAs on the hospital ward. Although some nurses were already convinced of the added value that PTAs could bring to tasks such as patient admission and discharge, they uniformly expressed that such an expansion of the role could only be considered viable and effective when there are PTAs assigned to the hospital ward. This continuity, they believed, is crucial in establishing a deeper understanding of the ward's dynamics and developing a level of trust and knowledge necessary for additional responsibilities.

Nurse 4: "I think it would be a whole different story if you have one or two PTAs permanently employed on your hospital ward. When you look at the whole concept of admission, hospitalization and discharge, you look at a competency profile of what a PTA is on our ward."

3.3. Patient Safety and Quality of Care

3.3.1. Nurses' Time Saving and Decreased Workload. Nurses expressed a consistent perspective that the implementation of PTAs not only has resulted in a saving of nurses' time but has also given them the opportunity to redirect their focus to other critical aspects of patient care and contribute to the overall quality of care provided. All participants mentioned a reduced nursing workload on pharmaceutical care. They indicated that this shift in responsibilities enabled them to make more patient rounds, allocate more time for the admission of new patients, and dedicate more attention to individual direct patient care. In addition, it provided the flexibility to engage in meaningful conversations with patients who may benefit from such interactions, addressing their emotional and psychosocial needs.

Nurse 4: “For our night nurses, it’s a return of, I think, two thirds of the medication preparation time.”

Nurse 11: “I think that’s a good thing. Because during the night. . . For example, last week I had two seriously ill people on my ward. I had the opportunity to check on them every two hours, which I couldn’t do before.”

Nurse 16: “It’s just a heavy weight that has been lifted from your shoulders during the night. . . you also have more time for the patients as well.”

3.3.2. Lower Risk of Medication Errors. The participants described the challenges faced by night nurses, who are frequently disturbed by patient calls, medication rounds, and overnight admissions. These factors, in combination with natural daily rhythm, are seen to contribute to a greater risk of reduced alertness during night shift hours. Recognizing potential risks, particularly related to the dispensation of medication and its higher risk of medication errors, participants believed that PTAs decrease the risk of errors because they are dedicated to the singular task of medication dispensing during their time on the hospital ward.

Nurse 3: “They (PTAs) can be specifically working on that, they work on their medication for two hours continuously. The night nurse has never been able to do that, meanwhile there are patient calls, someone doesn’t get well. . . They (PTAs) are doing that, they are not being disturbed by anyone, so you will certainly have fewer mistakes than you are constantly distracted.”

Nurse 4: “I think, according to the time of night, the workload, the whole patient care you are doing, you are not always alert to prepare medication during the night. A PTA is to focus on one task, which is always an added value.”

3.3.3. Creating a Relationship of Trust and Developing Competencies. As mentioned in the previous theme, all participants considered it important to consistently assign the same hospital wards to the same PTAs. This approach has several advantages, offering PTAs an in-depth understanding of prevalent pathologies, improving clinical reasoning skills, and fostering team integration. Some head nurses proposed the idea of permanently stationing one or two PTAs on the hospital ward; in their belief, this could bring additional value to the nursing team by cultivating even stronger relationships, efficient communication, and ensuring a consistently high level of expertise in medication management.

Nurse 13: “It would be more ideal, I think, if we had someone on the ward who was a member of the team and was actually fully in charge of the medication from preparation to administration of the medication.”

Nurse 14: “I really hope they are going to be permanent people who work there, what would make sense. Because you know each other in the long run. You can tune into

each other and you know what to expect from each other. If it’s someone else every time, you don’t know either.”

4. Discussion

In exploring nurses’ views on the implementation of PTAs for medication dispensation on hospital wards, three main themes have emerged: “organization of medication management,” “patient safety and quality of care,” and “role development and collaboration.” PTAs are valuable resources to provide safe, efficient, and high-quality pharmaceutical care.

In the theme “*organization of medication management*,” facilitators and barriers were identified. Clear protocols, comprehensive training, PTA supervision, and efficient task allocation streamlined the process, reducing nurse workload, and improving efficiency. Regarding continuity in assigning PTAs, the disparities in perspectives reflect the dynamic and context-specific nature of healthcare settings. Optimal scheduling and PTA allocation depend on factors, such as patient awareness, ward specialization, and demand for nursing care at different times. On the contrary, the barriers included inadequate PTA numbers and possible medication errors due to a lack of standardized procedures. To enhance this aspect, healthcare organizations should consider investing in resources and establishing standardized procedures. This might involve ensuring an adequate number of PTAs and implementing clear guidelines for their role. By doing so, organizations can optimize the integration of PTAs into nursing practices, thus improving overall medication management [26].

The second theme, “*role development and collaboration*,” emphasized a unified healthcare team. Facilitators, such as clear scopes of practice for PTAs, collaborative work environments, and mutual respect between PTAs and nurses, improve collaboration and task transition [27]. However, barriers such as role ambiguity, inadequate nurse-PTA communication, and resistance to new responsibilities can impede this collaboration.

The third theme, “*patient safety and quality of care*,” highlighted the advantages of implementing PTAs in maintaining high standards of patient safety. Kjeldsen et al. [15] reported that the dispensation of medication by PTAs on a geriatric ward resulted in reducing interruptions, dispensing time, and reported medication errors. Miscommunication between nurses and PTAs could pose a threat to high-quality medication management. Therefore, healthcare teams must prioritize effective communication, double-check procedures, and continuous training to improve patient safety and quality of care [28, 29].

Implementing PTAs on hospital wards presents a multifaceted opportunity for nursing management. While the practical benefits are undeniable, ensuring successful integration requires a comprehensive approach. Beyond facilitating collaboration and fostering communication, nursing managers must navigate ethical considerations and provide adequate training for PTAs. Addressing potential challenges like role ambiguity and proactively managing interprofessional relationships are also crucial [30].

Continuously evaluating the impact of PTAs on patient outcomes and healthcare delivery efficiency allows for optimizing their contribution. By embracing this broader perspective, nursing management can unlock the full potential of PTAs, ultimately enhancing patient care, staff satisfaction, and the overall healthcare delivery system [31, 32].

To prevent missed nursing care, such as patient self-management support, education, psychological support, and shared decision-making, and to promote interprofessional collaboration, team members should have a clear understanding of each role. Creating a cohesive collaboration among nurses, physicians, and pharmacists is crucial to improve the quality of pharmaceutical care and ultimately improve patient outcomes. A precise description of the role of pharmaceutical care is necessary. The NuPHAC-EU framework was developed for this purpose, describing the role of nurses in pharmaceutical care, encompassing patient, and professional networks in seven domains with 26 tasks. Nurses can carry out tasks with varying degrees of autonomy based on contextual factors. This framework provides a structured approach and facilitates discussions among healthcare professionals about shared responsibilities and tasks. Adopting this framework within healthcare organizations can help redefine the roles and responsibilities of nurses and PTAs. It encourages transparent communication among a variety of healthcare professionals and provides essential support during role transitions through comprehensive education and training initiatives [28].

Previous studies on the collaboration between the PTA and nurses suggest a lower risk of medication errors and improved quality of care [12–15]. The perspectives of nurses in this study support the idea that this collaboration is beneficial in healthcare settings. However, to fully optimize PTAs implementation on hospital wards, it is imperative to investigate the experiences and perceptions of these PTAs. Understanding their perspectives, challenges, and insights can provide valuable information to refine the integration process, address potential barriers, and maximize the positive impact of PTAs in medication management within healthcare settings.

This study did not directly measure effects, but the existing literature suggests potential benefits of implementing PTAs, including cost savings, increased nursing time for (in)direct patient care activities, and potentially improving workflow efficiency [12–15, 29, 33]. To understand the PTAs' impact, future research exploring measurable effects, cost implications, and broader outcomes could provide additional information on their effectiveness and contribution to healthcare settings.

Although interviews were conducted across various hospital wards, representing different specialities such as internal medicine, surgery, and geriatrics, focusing on the implementation of PTAs within a single healthcare organization limits the generalizability of the findings to other healthcare settings. However, by exploring the experiences and perspectives of nurses within this specific context, this study offers valuable insights that can contribute to theoretical generalization with caution. These findings may not

be directly applicable to all healthcare settings, particularly those with different cultural contexts, organisational structures, policies, or practices. Nevertheless, the identified themes can provide valuable inspiration and transferable knowledge for other healthcare organizations considering the implementation of PTAs on their hospital wards. This limitation emphasizes the need for further research that encompasses multiple healthcare organizations or settings to provide a more comprehensive and diverse understanding of the implementation and perceptions surrounding PTAs in medication management.

To ensure the robustness of our data analysis and findings, a variety of rigorous methods and techniques were used. Triangulation involved a meticulous cross-validation process. This regular cross-check meetings between the two researchers allowed for critical and sense-making discussion of data interpretations. In addition, discussions within the project group provided a valuable collaborative perspective that served to validate the findings and mitigate potential bias. Furthermore, the thematic presentation and discussion of the themes with the participants were important to maintain the authenticity of our interpretations. This interactive dialogue provided a deeper exploration of the participants' experiences and insights, reducing the risk of superficial or false interpretations, and ensured that the data analysis was embedded in the participants' experiences.

5. Conclusion

This study provided a comprehensive understanding of nurses' perspectives on the implementation and advancement of the role of PTAs in the dispensation of medications on the hospital ward. The recognition of PTAs by nurses as valuable contributors in medication management highlights their potential to positively impact healthcare settings. Understanding and embracing this perspective could facilitate further integration and optimization of PTAs within hospital wards, benefiting both healthcare professionals and, most importantly, the patients they serve.

Data Availability

The data used to support the findings of this study are available from the corresponding author upon reasonable request.

Disclosure

The hospital and the University Foundation from Belgium did not play a role in the design of the study, data collection, analyses, interpretation of the results, or the development and submission of the manuscript.

Conflicts of Interest

MDG, BS, and VR are Vitaz employees (General Hospital—Belgium) and received a part-time salary for this study. The remaining authors have no conflicts of interest to declare.

Acknowledgments

The Clinical Nursing and Allied Health Research and Development Group and the authors of this study would like to express their gratitude to Vitaz (General Hospital—Belgium) for their participation, resources, and financial support in the study. The authors would like to offer great appreciation to all participating (head) nurses for sharing their perceptions. The authors acknowledge the University Foundation from Belgium for their financial support in the publication of this work.

Aims. Building on conservation of resources theory, our study investigates how inclusive human resource management (IHRM) promotes nurses' innovative behavior through job crafting and further examines the moderating role of shared leadership. **Background.** Nurses' involvement in innovation is essential to improve nursing care delivery and accommodate changing medical environments, especially in the face of crisis events like the COVID-19 outbreak. However, knowledge about the relationship between human resource management and nurses' innovative behavior remains scarce. **Methods.** We collected three-wave data from 338 on-duty registered nurses at four public hospitals in China from November 2022 to January 2023. We used SPSS 22 to conduct hierarchical regressions to test our hypotheses. **Results.** IHRM positively predicted innovative behavior of nurses with the mediating role of job crafting. In addition, we found that IHRM was more effective in promoting job crafting and subsequent innovative behavior when nurses perceived high levels of shared leadership. **Conclusion.** IHRM initiated by the organization and shared leadership style are two collaborative approaches to facilitating nurses' job crafting, thereby responding to the imperative need to foster nurses' innovative behavior. **Implications for Nursing Management.** The present study emphasizes the important roles of IHRM and shared leadership in promoting nurses' job crafting and subsequent innovative behavior, providing theoretical and practical implications for nursing management in the current dynamic and challenging environment.

1. Introduction

In today's competitive and technologically advanced medical environment, the survival and growth of healthcare organizations depend on their ability to innovate [1]. Hospital innovation is driven by the knowledge and innovative engagement of nursing staff, who contribute by introducing new ideas, acquiring new knowledge, generating new ideas, improving current processes, and discovering new technologies [2]. During public health emergencies like the COVID-19 outbreak, nursing staff not only face increased risks of infection and heavier workloads but also need to adapt to new working styles and optimize treatments to achieve healthcare goals [3]. Hence, it holds immense theoretical and practical significance to investigate how to

develop the potential of frontline nurses in elevating the quality of nursing care to overcome major crises that healthcare organizations may encounter [4].

Innovative behavior refers to the intentional generation, promotion, and implementation of new ideas within a work role, group, or organization to enhance role performance [5]. Highly innovative employees can quickly respond to client needs, generate valuable ideas, and optimize processes, which are essential for improving organizational efficiency and effectiveness [6]. In the nursing field, Zhang et al. [7] conceptualized nurses' innovative behavior as generating new ideas, overcoming challenges and obstacles to realize them, and developing new treatment protocols or policies to restore and promote the health of their patients. Workforce aging, the increasing expectations for high-quality care, and

the demand for cost-effectiveness impose greater requirements on healthcare organizations to innovate [8]. In this context, a comprehensive understanding of the drivers behind nurses' innovative behavior is critical for the advancement of healthcare.

Although innovative behavior has provoked extensive attention from scholars in business, education, and project management [2, 9, 10], only a limited number of empirical studies have investigated how to promote nurses' innovative behaviors during crisis events [8]. Furthermore, the majority of these studies has primarily focused on leadership styles, such as servant leadership, humble leadership, and transformational leadership, as antecedents [6, 7, 11], while neglecting the influence of organizational factors, such as human resource management (HRM) practices, on nurses' innovative behavior. However, it is widely acknowledged that innovative behavior is considered discretionary extra-role behavior for most nurses and requires tangible and intangible support from the organization to be sustained (e.g., pay and rewards, an innovative climate, and job autonomy [12]). Numerous studies have shown that HRM practices play a crucial role in enhancing employees' abilities, motivation, and opportunities, thereby influencing their attitudes and behaviors towards innovation [13, 14]. Recognizing the importance of developing relevant theories of HRM practices to encourage innovation in hospitals, Renkema et al. [15] underscored the need for further research in this area. As such, our study contributes to the literature by focusing on the discernible role of inclusive human resource management (IHRM) in promoting innovative behavior among nurses.

During crisis events such as pandemics, frontline nurses face increased psychological and physical demands due to infection control, complex doctor-patient relationships, and occupational hazards during isolation [3, 16]. According to the conservation of resources (CORs) theory, the stressful and threatening environment will pose an intense strain on individuals and consequently lead to potential or actual resource losses, which make individuals typically conserve the limited resources available for innovative behavior [17]. In contrast, a well-resourced organizational context shaped by specific management practices can alleviate individuals' strain and increase their willingness to utilize current resources to engage in innovative activities [18]. As a result, healthcare organizations need to provide nurses with external resources to address stressful demands and reduce the uncertainty of innovation through understanding, respect, and appreciation [19]. IHRM values individuals' differences and unique contributions, treats nurses in a fair and equal way, encourages participative decision-making, and helps nurses adapt to the organization [14]. The support provided by IHRM makes nurses feel that the organization appreciates their competence, invests in their development, and cares about their wellbeing [20], and thus they will proactively conduct innovative behavior in public health emergencies.

The COR theory also suggests that individuals proactively seek to acquire valuable resources through investment to realize the incremental value of the resources [21]. As such, we expect that people are more likely to

engage in proactive behavior when they have sufficient resources available to them [17]. Job crafting, which refers to individuals initiating changes in job demands and resources to align with their abilities and needs [22], has been recognized as a proactive behavior that enhances nurses' engagement in innovation [9, 23, 24]. Job crafting is particularly advantageous to healthcare organizations as these skills can be easily acquired and transferred through training and practical experience in an organizational context [25]. IHRM provides nurses with access to more information and resources, increases their participation and sense of control, and allows them to accumulate knowledge and skills [12, 26]. As a result, nurses are more motivated to craft their jobs, which can significantly impact their innovation [18]. Therefore, job crafting may be a crucial mechanism that transforms the resources provided by IHRM into innovative behavior among nurses.

As previously mentioned, nursing leadership is the key to inducing nurses' innovative behavior and transformative change in hospitals [27]. Informal leadership roles serve as the driving force for nurses to generate novel ideas, set new goals, and implement useful techniques [11], and exploring new insights into nursing leadership helps to tackle varied drivers in the multiple contexts of modern healthcare [28]. Our study complements the research by highlighting the interaction between IHRM adopted by the organization and shared leadership among unit nurses in healthcare delivery. Chen et al. [29] denoted that shared leadership is a dynamic process of interaction among members aiming to achieve unit and/or organizational goals, where members work together to set goals, make decisions, learn and mentor, and support and encourage each other [30], and thus, it can be synergistic with IHRM to generate valuable resources for nurses to craft their job and engage in innovate behavior.

In summary, this study aims to construct a moderated-mediation model (see Figure 1) to examine the internal mechanism and boundary condition of IHRM influencing innovative behavior among nursing staff. Specifically, we seek to answer the following three research questions: (a) whether IHRM can be a critical facilitator of nurses' innovative behavior, (b) whether job crafting can mediate the relationship between IHRM and innovative behavior, and (c) whether shared leadership can amplify the positive effects of IHRM on job crafting and nurses' innovative behavior. We tested our hypotheses through a time-lagged study where questionnaires were administered to registered nurses from four public hospitals in Wuhan between November 2022 and January 2023. The findings from our research can (a) contribute to the literature on the multilateral factors influencing nurses' innovative behavior and the theoretical rationale underlying the relationship between IHRM and nurses' innovation and (b) provide insights for HR practitioners in healthcare to adopt appropriate HRM policies and practices and develop interventions that promote shared leadership and job crafting, thus fostering nurses' innovative behavior.

FIGURE 1: Hypothesized moderated mediation model.

2. Theory and Hypotheses

2.1. IHRM and Nurses' Innovative Behavior. IHRM originates from the concept of inclusion and has received widespread attention from scholars over the past two decades. Inclusion, from a leadership perspective, refers to the leader's words and actions that demonstrate an invitation and appreciation for employee contributions [16]. From an involvement perspective, inclusion represents individuals perceiving themselves as part of the organization's key processes [26]. Relationally, inclusion entails building strong relationships with employees and encouraging their participation [31]. From an equity standpoint, inclusion means that employees have the right to express themselves and be appreciated regardless of their social status or class [32]. Taking the optimal distinctiveness perspective, Shore et al. [20] identified inclusion as the extent to which employees feel respected in their work teams based on how well the organization fulfills their need for belongingness and uniqueness. Building on the abovementioned literature, IHRM reflects multiple inclusion-based practices including fair employment policies, participatory decision-making, employee recognition and acceptance, diverse value stimulation and utilization, and rights respect and empowerment [33]. Zhao et al. [14] defined IHRM as a series of interdependent HRM policies, functions, and practices that respect employee differences, recognize employee contributions, accommodate employee mistakes, realize employee strength, encourage employee involvement, and constrain interpersonal conflict to achieve organizational goals. Prior studies identify IHRM as a holistic system consisting of diverse selection (e.g., recruiting heterogeneous employees with multiple knowledge and skills [12]), personalized configuration (e.g., valuing and leveraging employee differential strengths [13]), inclusive development (e.g., providing diversified skills training [34]), participatory assessment (e.g., encouraging participation in the formulation of performance indicators [35]), and targeted compensation (e.g., establishing equal pay system, decent salaries, and good benefits [26]). IHRM ascertains that employees are appreciated and rewarded for their contributions and treated equitably across different position levels [16], and scholars have proven its plausibility in relation to employee creativity [14], wellbeing [12], and job satisfaction [35] within the organization.

Nurses' innovative behavior refers to the process of changing routines or employing new methods and technologies to optimize workflow and enhance patient satisfaction with healthcare delivery [1]. The International Council of Nursing (ICN) recognizes that nursing innovation encompasses the following three phases: idea generation, idea promotion, and idea implementation, and emphasizes its important role in promoting wellness, preventing disease, and improving the quality of healthcare [6]. Innovation is a complex and prolonged process that continuously consumes nurses' psychological, physical, and knowledge resources [4]. During crisis events, healthcare workers experience immense pressure to maintain emotional composure while dedicating themselves to patient care, which often leads to mental dissonance and continued loss of resources [3, 16]. The COR theory postulates that people are motivated to protect their current resources and acquire new resources to defend themselves against future resource loss [18]. As a result, nurses may reduce high-risk innovative behavior if they are aware of potential or actual resource loss [17]. Therefore, it is important to provide nurses with sufficient resources to supplement what has been depleted to promote their innovative behavior [21]. Previous research has confirmed that the workplace represents a proximate environment in which employee resource pools and associated work outcomes are affected by HRM practices [12]. In this vein, IHRM can be viewed as a source of resources for nurses to cope with highly demanding work, which can effectively compensate for nurses' loss of resources and enable them to possess sufficient psychological resources to innovate during crisis events [20].

Specifically, the diverse selection of IHRM emphasizes the need for hospitals to construct multifaceted talent teams, with nurses' gender, age, education, and experience structure displaying a certain degree of complementarity [36]. Nursing staff with various experiences and backgrounds are more likely to form differentiated knowledge structures and critical thinking patterns. These heterogeneous cognitive resources are conducive to the formation of nurses' open-minded visions, which in turn inspire them to develop and implement novel and useful ideas to improve service methods that benefit the patients [33]. Meanwhile, inclusive development focuses on individualized training for nurses to provide them with knowledge and skill resources [35], such as professional knowledge, clinical skills, technology proficiency, emergency response, and communication skills, which are

critically needed to cope with creative requirements. Participatory assessment empowers nurses to engage in the decision-making process and tailor performance appraisal approaches based on specific job characteristics. This practice ensures that nurses feel their viewpoints are respected and have access to organizational information resources, thus significantly enhancing their motivation to conduct innovative behaviors [31]. In addition, IHRM advocates the application of flexible work systems such as shift changes, rotations, and leave transfers in the task allocation process and gives nurses a sense of autonomy through empowerment practices [13]. Job flexibility and autonomy provided by personalized configuration allow nurses to proactively engage in innovative behavior such as creative problem solving to realize resource augmentation [37]. Finally, one's commitment to risky creative activities requires the necessary incentives and support, and favorable compensation and benefits can effectively hedge the risk of loss associated with innovation [26]. Targeted compensation adjusts compensation levels, structures, and strategies in response to feedback from nursing staff to ensure that each nurse's contribution can be valued and rewarded. Sufficient material resources constitute a critical prerequisite for promoting nurses' readiness and willingness to innovate [38]. In summary, IHRM practices serve as valuable resources invested by healthcare organizations to increase nurses' resource stock (e.g., enhancement of professional skills, increase in reward, and reduction of role ambiguity [12]) through diverse selection, inclusive development, personalized configuration, participatory assessment, and favorable compensation. As such, nurses with adequate resources (e.g., support from the hospital, training, and development opportunities) will generate more ideas about public health and nursing service and put them into practice [17]. Thus, we hypothesize the following.

Hypothesis 1. IHRM positively affects nurses' innovative behavior.

2.2. The Mediating Role of Job Crafting. Job crafting is a bottom-up approach to autonomous job redesign that diverges from the top-down approach typically implemented by organizations and places emphasis on employees' initiative to make changes in their work [39]. Following the job demands-resources model, research has identified the following four types of job crafting [22]: increasing structural job resources (diverse resources and autonomy to help employees achieve their goals), increasing social job resources (social support and feedback from managers, colleagues, and others), increasing challenging job demands (accomplish more difficult tasks to improve knowledge and skills), and decreasing hindering job demands (mitigate resource depletion when faced with excessive demands). Nurses who engage in job crafting proactively align their talents, strengths, and interests with their work environment, enabling them to achieve a balance between job demands and resources [23, 25].

We draw on the COR theory to scrutinize how IHRM influences nurses' innovative behavior by fostering their job crafting. The COR theory highlights human's evolutionary need to conserve and acquire resources for survival that is central to the genetics of human behavior [17]. A fundamental principle of the COR theory relates to the notion of resource investment, that is, when people possess sufficient resources, they tend to proactively invest resources in behaviors designed to compensate for prior resource losses or to acquire additional resources [18]. Consistent with this postulation, employees tend to engage in job crafting to invest their resources to create a better work environment when a resource surplus occurs [21]. As earlier mentioned, IHRM implemented by the healthcare institution creates a resourceful organizational context for nursing staff [12]. We, therefore, expect that job crafting can be regarded as an agentic behavior of resource investment that provides individuals with beneficial ways to utilize and transform useful resources derived from IHRM to achieve a positive resource gain spiral [18], such as generating energy, self-efficacy, interpersonal capital, and diverse skills that make employees more resilient to resource loss and more willing to undertake the risks of innovative behavior [40].

We first argue that IHRM can stimulate job crafting among nurses by supplying them with sufficient job resources [39]. IHRM allows nurses to exert considerable influence over organizational decisions and gives them access to more information and resources [14], which largely increases nurses' sense of control and further facilitates their job crafting. Furthermore, training and rotations provided by IHRM enable nurses to accumulate knowledge, skills, and abilities to improve their occupational competence and job performance [34]. Research has demonstrated that individuals with higher occupational competence are more likely to craft their job in a more skillful and professional manner [41]. Nurses who have occupational competence as an available resource can feel more comfortable crafting the way they work. More importantly, Van Wingerden and Poell [42] have emphasized that the opportunity for job crafting is an indispensable factor in influencing individuals' decisions to engage in this behavior. IHRM makes nurses perceive more opportunities to alter their job by providing greater job autonomy. For instance, organizations grant nurses specific job authorizations and autonomy in their work arrangements, allowing them to choose appropriate training, performance evaluation approaches, and benefits tailored to individualized needs. Taken together, we propose that nurses perceiving high IHRM will proactively engage in job crafting based on their talents, interests, and strengths [23]. Thus, we hypothesize the following.

Hypothesis 2. IHRM is positively related to nurses' job crafting.

We further predict that job crafting can positively influence nurses' innovative behavior because job crafting is a proactive behavior that provides nurses with opportunities to access useful resources that promote work goal attainment while reducing obstructive job demands that deplete physical and psychological resources [19]. Specifically,

structural job resources such as increased discretion in work enable nurses to decide how to perform tasks independently and provide them with more chances to try different techniques, methods, and procedures to solve complex medical problems [40], which improves nurses' feeling of obligation to innovate [4]. Social job resources such as head nurses' support can help nurses acquire and accumulate emotional resources that reduce the innovation risk and prevent nurses from falling into the loss spiral due to resource shortage [43]. In line with the COR theory, nurses who possess plentiful material and emotional resources face less pressure at work and are more inclined to exhibit innovative behaviors to enhance self-worth [18, 42]. Meanwhile, increasing challenging job demands can significantly promote job vitality, which to some extent enhances individuals' cognitive flexibility and improves nurses' creative thinking during crisis events [44]. Hindering job demands that impede nurses' growth and development, such as role conflict and bureaucracy, may prevent the optimal functioning of tasks, bring unnecessary stress, and lead to negative emotions in nursing staff [25]. When individuals experience a loss of resources at work, they will adopt a defensive attitude towards behaviors that consume resources [21]. Job crafting avoids resource loss by reducing obstructive job demands, further promoting innovative behaviors among nurses. Taken together, job crafting can promote nurses' innovative behavior by simultaneously facilitating a "resource gain path" that increases job resources and challenging job demands, and inhibiting a "resource loss path" that generates obstructive job demands [19, 22]. Thus, we hypothesize the following.

Hypothesis 3. Job crafting is positively related to nurses' innovative behavior.

Based on the arguments above, we expect that IHRM provides a platform for nursing staff to acquire resources that enhance their abilities, motivation, and opportunities for job crafting, which in turn promotes their innovative behavior. Thus, we hypothesize the following.

Hypothesis 4. Job crafting mediates the positive relationship between IHRM and nurses' innovative behavior.

2.3. Shared Leadership as a Boundary Condition. Shared leadership, as an emerging leadership style, refers to a group dynamic interaction process whereby different members are selected to assume leadership roles at different stages according to changes in the external environment and group members' strengths to achieve the common goals of the group [45]. Leadership style directly affects the nurses' perception and interpretation of HRM practices and further influences their attitudes and behaviors [46]. Shared leadership delivers consistent signals with IHRM that team members are encouraged to participate in decision-making and extensive information sharing [47], making nurses feel a sense of autonomy and initiative to utilize the resources from IHRM for job crafting and innovative behavior [48].

In this sense, we expect that shared leadership may reinforce the positive relationship between IHRM and job crafting. Research has identified leadership style as the contextual force that enables or constrains the eventual implementation of job crafting [27]. Shared leadership dynamically shifts leadership responsibilities among group members based on their expertise and competencies in relation to specific task situations [29]. It allows nurses to break away from the constraints of their previous roles and routines so that they can try out various work methods, fully develop their potential, and improve their efficacy [45]. Thus, nurses under high shared leadership have a higher sense of competence and believe that they can better utilize the opportunities provided by IHRM to craft their job [32]. In addition, since job crafting is the readjustment and optimization of nurses' tasks and relationships related to their work, this process involves the change of the original work pattern and approach, which may be impeded and constrained by their colleagues [49]. Shared leadership breaks down the traditional interpersonal interaction pattern among group members [30], and nurses engage in frequent exchanges and interactions with colleagues to form a sharing, reciprocal, and harmonious relationship [28]. Under high shared leadership, nurses seldom encounter obstacles and constraints from their colleagues and tend to utilize the resources provided by IHRM to conduct job crafting [47]. In contrast, although IHRM enhances nurses' abilities, motivation, and opportunities for job crafting, nurses under low shared leadership lack a sense of competence and are hindered by colleagues, which prevent them from job crafting. Thus, we hypothesize the following.

Hypothesis 5. Shared leadership moderates the relationship between IHRM and job crafting such that this positive relationship is stronger when shared leadership is high (vs. low).

As previously mentioned, shared leadership accentuates the positive impact of IHRM on nurses' job crafting through power and responsibility sharing, team learning, member support, and mutual skill development, and job crafting provides nurses with more resources to engage in innovative behavior [24]. In contrast, nurses who perceive low shared leadership are less likely to utilize the resources derived from IHRM to craft their job and display innovative behavior. Thus, we hypothesize the following

Hypothesis 6. Shared leadership moderates the indirect effects of IHRM on nurses' innovative behavior via job crafting such that this indirect effect is stronger when shared leadership is high (vs. low).

3. Method

3.1. Sample and Procedure. We collected data from on-duty registered nurses at four public hospitals in China. Researchers contacted the chiefs of nursing staff at four public hospitals in Wuhan that are top in healthcare services and medical technology and explained the

purpose and procedures of the study to obtain permission. With the assistance of head nurses, a disclosure statement was delivered to the nurses who participated in the questionnaire survey, including the academic purpose of our research, the principles of voluntariness, anonymity, and confidentiality, which would constitute the informed consent of nurses to participate in the investigation. Nurses participating in the study should meet the following criteria: (a) above 18 years of age; (b) hold a Chinese registered nurse license; and (c) work full time. We excluded nursing staff not directly involved in patient care and who were on leave, such as maternity, sick, and vacation leave. Our research adopted a time-lagged design to collect data at 3 time points with a 1-month interval to minimize the influence of common method variance [50]. Participants responded to the questionnaire items measuring the predictors (IHRM and shared leadership), mediator (job crafting), and outcome variable (innovative behavior) at time points 1, 2, and 3, respectively, and the self-generated anonymous codes were used to guarantee the effective match of the three-wave survey.

Data were collected from November 2022 to January 2023 during the reopening of the epidemic. Table 1 presents the data collection procedures. In light of the population mobility constraints imposed by the epidemic in China, we utilized online methods to collect data and emailed a link with the questionnaire to participants. At Time 1, we sent questionnaires to 400 nurses at four hospitals and asked about their demographics, perceived IHRM, and perceived shared leadership. We received 374 responses. At Time 2, nurses who had completed the Time 1 survey measured job crafting. 352 valid questionnaires were returned. At Time 3, the remaining 352 nurses reported their innovative behavior. We received 345 completed questionnaires. After eliminating 7 invalid questionnaires due to missing and unmatched data, we ultimately obtained a valid sample of 338 nurses, yielding a response rate of 84.5%. Table 2 presents the participants' demographic characteristics. Among the participants, 22.2% were male and 77.8% were female. 18.3% were 25 years old or below, 49.1% were in the 26–35 age range, 29.0% were in the 36–45 age range, and the remaining 3.6% were 46 years old or above. 37.6% reported an associate's degree or below, 53.3% had a bachelor's degree, and the remaining 9.1% had a master's degree or above. 29.9% had 2 years of experience or below, 25.7% had 3–5 years of experience, 27.8% had 6–7 years of experience, and 16.6% had 8 years of experience or above. 47.3% were nurses, 38.5% were senior nurses, and 14.2% were supervisor nurse or above.

3.2. Measures. All measures utilized in this study were drawn from prior research and have been demonstrated to possess satisfactory reliability and validity over time. A 5-point Likert scale was adopted to measure all items, ranging from 1 (strongly disagree) to 5 (strongly agree). The definitions and measures of the variables are presented in Table 3.

3.3. IHRM. IHRM was measured using 20 items adapted from Zhao et al. [14] in the Chinese context. This scale included the following five dimensions: diverse selection (five items, e.g., “in my organization, there is no discrimination against gender, age, ethnicity, religion, nationality, and dialect during recruitment and selection”), personalized configuration (five items, e.g., “My organization considers job demands, nurses' needs, and strengths during task assignment”), inclusive development (five items, e.g., “my organization provides differentiated and individualized training programs to meet the various needs of nurses”), participatory assessment (five items, e.g., “in my organization, performance appraisal emphasizes results feedback, problem diagnosis, and recommendation solicitation”), and targeted compensation (five items, e.g., “compared with similar positions in other hospitals, the compensation offered by my organization is fair and reasonable”). Cronbach's α was 0.930.

3.4. Shared Leadership. Shared leadership was assessed using 16 items from Hoch and Kozlowski [30]. This scale consisted of the following three dimensions: team learning (four items, e.g., “our team actively searches our own performance for deficits”), perceived team support (five items, e.g., “my team really cares about my wellbeing”), and member-member exchange (seven items, e.g., “my team understands my problems and needs”). Cronbach's α was 0.941.

3.5. Job Crafting. We measured job crafting using 21 items from Cheng et al. [25], which had been validated among nurses in public hospitals in China. The scale consisted of the following four dimensions: increasing structural job resources (five items, e.g., “I make sure that I use my capacities to the fullest”), increasing social job resources (five items, e.g., “I ask others for feedback on my job performance”), increasing challenging job demands (five items, e.g., “If there are new developments, I am one of the first to learn about them and try them out”), and decreasing hindering job demands (six items, e.g., “I make sure that my work is mentally less intense”). Cronbach's α was 0.848.

3.6. Innovative Behavior. We measured nurses' innovative behavior using a 6-item scale adapted from Scott and Bruce [5]. A sample item was “in my work, I will actively seek new methods, techniques, and procedures.” Cronbach's α was 0.928.

3.7. Control Variables. Following previous research on innovative behavior [10, 11], control variables of nurses' gender, age, education, and experience were included.

3.8. Analytical Approach. We used SPSS 22 to conduct hierarchical regressions to test our hypotheses. Specifically, we constructed regression models, respectively, with job crafting and nurses' innovative behavior as dependent variables to estimate the standardized regression coefficients

TABLE 1: Data collection procedures.

Research design	Time points	Data collection period	Evaluator	Variables	Questionnaires distributed	Valid questionnaires returned
Time-lagged questionnaire survey	Time 1	1 November 2022–3 November 2022	Nurse self-report	Demographics, IHRM, and shared leadership	400	374
	Time 2	1 December 2022–3 December 2022	Nurse self-report	Job crafting	374	352
	Time 3	1 January 2023–3 January 2023	Nurse self-report	Nurses' innovative behavior	352	338

TABLE 2: Demographic characteristics of the participants.

Variable	N	%
Gender		
Female	263	77.81
Male	75	22.19
Age (years)		
≤25	62	18.34
26–35	166	49.11
36–45	98	29.00
≥46	12	3.55
Education		
Associate's degree or below	127	37.57
Bachelor's degree	180	53.26
Master's degree or above	31	9.17

Senior nurses	130	38.46
Supervisor nurse or above	48	14.20

between main variables. To test the moderating effects, we created an interaction term by mean centering IHRM and shared leadership and performed the simple slope tests following Aiken and West's [51] procedures. Finally, we conducted bootstrap analyses to generate 95% bias-corrected confidence intervals (CIs) for mediation and moderated mediation effects using Hayes' [52] PROCESS macro. The moderated mediation effect was significant if 95% CI of difference between the indirect effects under high (+1 SD) and low (−1 SD) levels of the moderator excluded 0.

4. Results

4.1. Confirmatory Factor Analyses (CFA). We compared measurement models through a series of CFAs using Mplus 8.0. As shown in Table 4, the expected four-factor model yielded a good fit to the data ($\chi^2(98) = 269.189$, CFI = 0.949, TLI = 0.937, RMSEA = 0.072, and SRMR = 0.031) and the hypothesized model fit the data better than the alternative models with fewer factors, indicating that there was an acceptable discriminant validity between the focal variables.

4.2. Common Method Variance (CMV). Following Podsakoff et al.'s [50] recommendations, we first performed Harman's single-factor test to examine the CMV. The results of exploratory factor analysis (EFA) indicated that the first common factor only accounted for 27.1% of the variance, which was less than the threshold of 40% and less than half of the 69.2% of the total variance explained. In addition, results of the CFA showed that the goodness of fit of the five-factor model with an additional latent common method factor was not improved significantly ($\Delta\chi^2/df = 0.127$, $\Delta CFI = 0.011$, $\Delta TLI = 0.013$, $\Delta RMSEA = 0.008$, and $\Delta SRMR = 0.007$) than the expected four-factor model, revealing that the CMV of our study was no serious.

4.3. Descriptive Statistics and Correlations. The mean scores for IHRM, shared leadership, job crafting, and innovative behavior were 3.351 ± 0.718 , 3.613 ± 0.716 , 3.766 ± 0.393 , and 3.753 ± 0.697 , respectively. IHRM was positively correlated with nurses' innovative behavior ($r = 0.261$, $p < 0.001$) and job crafting ($r = 0.254$, $p < 0.001$). Furthermore, job crafting showed a significant positive correlation with nurses' innovative behavior ($r = 0.369$, $p < 0.001$), providing preliminary support for the hypotheses.

4.4. Hypothesis Testing. The results of hierarchical regression analyses are presented in Table 5. After controlling for nurses' gender, age, education, and experience, the coefficient of IHRM on nurses' innovative behavior was significant and positive ($\beta = 0.264$, $p < 0.001$; model 3), supporting Hypothesis 1. In support of Hypotheses 2 and 3, the results revealed that IHRM positively affected job crafting ($\beta = 0.257$, $p < 0.001$; model 1) and job crafting had a positive impact on nurses' innovative behavior ($\beta = 0.350$, $p < 0.001$; model 4). As shown in Table 5, after adding job crafting, the positive coefficient between IHRM and nurses' innovative behavior decreased from ($\beta = 0.264$, $p < 0.001$; model 3) to ($\beta = 0.186$, $p < 0.001$; model 5); however, job crafting was still positively related to nurses' innovative behavior ($\beta = 0.301$, $p < 0.001$; model 5). Thus, we concluded that job crafting partially mediated the impact of IHRM on nurses' innovative behavior. In addition, we used PROCESS macro to examine the statistical significance of the mediation effect. Bootstrap results revealed that the indirect effect of IHRM on nurses' innovative behavior via job crafting was significant (indirect effect = 0.078, 95% CI = [0.039, 0.121]), providing additional support for Hypothesis 4. As shown in Table 5, the interaction between IHRM and shared leadership positively affected job crafting ($\beta = 0.146$, $p < 0.01$; model 2). We further conducted the simple slope tests and plotted the moderating effect in Figure 2. The results showed that the link between IHRM and job crafting was significant and positive under high levels of shared leadership ($\beta = 0.158$, $p < 0.001$) but nonsignificant under low levels of shared leadership ($\beta = 0.044$, $p = 0.303$), supporting Hypothesis 5. Finally, we used the bootstrap approach to calculate the conditional indirect effect to test Hypothesis 6. The indirect effect of IHRM on nurses' innovative behavior through job crafting was significantly positive when shared leadership was high (indirect effect = 0.078, 95% CI = [0.027, 0.145]) but nonsignificant when shared leadership was low (indirect effect = 0.022, 95% CI = [−0.040, 0.079]), and the difference between the indirect effects was significant (difference = 0.057, 95% CI = [0.003, 0.128]), supporting Hypothesis 6. The hypothesized model and standardized regression coefficients are presented in Figure 3.

5. Discussion

Our research answered recent calls to shed light on multiple factors that affect nursing staff's innovative behavior [8, 15]. We conducted a time-lagged field study to investigate whether, how, and when IHRM could promote nurses' innovative behavior by focusing on the mediating role of job

TABLE 3: The definitions and measures of study variables.

Variable	Definition	Dimensions	No. of items	Source
IHRM	IHRM refers to a set of interdependent HRM policies and practices that respect employee differences, recognize employee values, leverage employee expertise, enhance organizational equity, and provide employees with autonomy, flexibility, and the necessary support	Diverse selection, personalized configuration, inclusive development, participatory assessment, and targeted compensation	20	[12, 14]
Shared leadership	Shared leadership depicts an interactive process characterized by collaborative decision-making and shared responsibility whereby group members lead each other to achieve goals	Team learning, perceived team support, and member-member exchange	16	[30]
Job crafting	Job crafting is defined as the changes made by employees to balance their job demands and job resources with personal abilities and needs in response to organizational change	Increasing structural job resources, increasing social job resources, increasing challenging job demands, and decreasing hindering job demands	21	[22, 25]
Nurses' innovative behavior	Innovative behavior refers to the intentional generation, promotion, and implementation of new ideas within a work role, group, or organization. Nurses' innovative behavior may manifest as incremental adjustments to current healthcare processes, services, and products or as innovative pragmatic solutions to restore and enhance patients' health	One dimension	6	[5, 7]

TABLE 4: Comparison of measurement models for study variables.

Models	Descriptions	χ^2	df	χ^2/df	Compare model differences	CFI	TLI	RMSEA	SRMR
Four-factor model	IHRM, SL, JC, IB	269.189	98	2.747		0.949	0.937	0.072	0.031
Three-factor model	IHRM, SL, JC + IB	439.090	101	4.347	$\Delta\chi^2(3) = 169.901, p < 0.001$	0.899	0.880	0.100	0.063
Two-factor model	IHRM, SL + JC + IB	967.325	103	9.392	$\Delta\chi^2(5) = 698.136, p < 0.001$	0.741	0.699	0.158	0.162
One-factor model	IHRM + SL + JC + IB	1868.844	104	17.970	$\Delta\chi^2(6) = 1599.655, p < 0.001$	0.472	0.391	0.224	0.189

Note. $N = 338$. IHRM = inclusive human resource management, SL = shared leadership, JC = job crafting, IB = nurses' innovative behavior. CFI = comparative fit index, TLI = Tucker-Lewis index, RMSEA = root mean square error of approximation, SRMR = standardized root mean square residual.

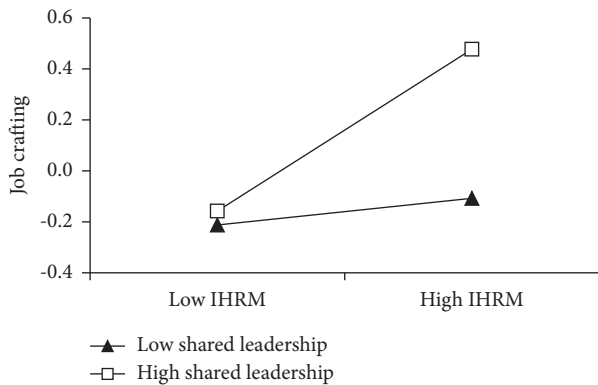

FIGURE 2: The moderating effect of shared leadership on the relationship between IHRM and job crafting.

crafting and the moderating effect of shared leadership. The results demonstrated that nurses perceiving higher levels of IHRM are more likely to engage in job crafting and consequently display more innovative behavior to improve current healthcare processes, services, and products during crisis events and this indirect relationship strengthens when nurses perceive higher shared leadership. Specifically, we obtained the following three findings which contribute to the existing HRM-innovation relationship literature.

5.1. Theoretical Implications

5.1.1. IHRM Is Positively Associated with Nurses' Innovative Behavior.

People's interpretations of inclusion and related practices may vary across cultures. In the Western context, scholars have mainly concerned with the fair and equal treatment of diverse employees, such as providing employees with opportunities to participate in organizational processes and decision-making through practices such as information sharing and employee involvement, thereby reducing discrimination and conflict inside and outside the organization [32, 36, 37]. However, inclusion in the Chinese culture (also known as *bao rong*) has a broader meaning that consists of two critical elements, "seeking commonalities" and "utilizing differences," highlighting the importance of making employees feel respected and integrated into the organization to experience a sense of belonging while preserving and utilizing employee uniqueness to optimize their personal strengths [26]. Therefore, IHRM may be more connected to employee creativity and innovation in the Chinese context [33]. Our results revealed a positive relationship between inclusive management practices and nurses' innovative behavior, which is aligned with the results of similar research conducted in business enterprises [14]. As such, our study extends previous literature by substantiating the applicability of IHRM to nursing staff in the healthcare field.

FIGURE 3: Hypothesized model with standardized regression coefficients. Note. $N = 338$. ** $p < 0.01$, *** $p < 0.001$.

However, the investigated hospitals in this study only achieved a medium level of IHRM (3.351 ± 0.718), which is lower than the findings of Zhao et al. [12] who examined knowledge-intensive companies. This suggests that healthcare organizations may lag behind in the development and implementation of HRM practices compared to business firms [8]. Considering the pressure, increasing need for innovation, and limited resources faced by nurses during a crisis, it is crucial for healthcare organizations to be more proactive in implementing IHRM to provide nurses with valuable physical, emotional, knowledge, and skill resources that support innovation [16, 18]. This study provides a theoretical foundation for these organizations to understand and develop relevant HRM policies that promote nurses' innovative behavior.

In addition, although a significant amount of research has focused on appropriate leadership styles as antecedents of nurses' innovative behavior, such as servant leadership, humble leadership, and transformational leadership [6, 7, 11], studies examining how organizational factors such as HRM policies and practices impact nurses' innovative behavior remain scarce. Accordingly, our research empirically confirms the crucial role of IHRM in facilitating innovative behavior, expanding studies on the antecedents of nurses' innovation and responding to the call from Renkema et al. [15] to explore nursing-related HRM theories to encourage innovation beyond leadership.

5.1.2. Job Crafting Mediates the Relationship between IHRM and Nurses' Innovative Behavior. The current study investigated the mediating process that transforms the beneficial impacts of IHRM into nurses' innovative behavior, and notably, the empirical evidence pertinent to this topic has primarily focused on employees' positive psychological states, such as psychological safety and psychological empowerment [8, 10]. Our findings help add to the current knowledge by demonstrating the mediating role of job crafting between IHRM and nurses' innovative behavior. Cheng et al. [25] reported that job crafting is increasingly recognized as an important concept in the nursing field, with its application expanding across different countries and it plays an essential role in improving nurses' person-environment congruence and wellbeing, especially during crisis events. Ghazzawi et al. [23] examined the role of

personality in the Arab World in predicting job crafting and confirmed the positive influence of job crafting on subjective wellbeing of nurses. However, there exists a knowledge gap regarding the relationship between HRM practices, job crafting, and innovative behavior among nurses. The resource investment principle of the COR theory provides a perspective for understanding this issue, which posits that people will proactively invest resources already acquired in the hope of obtaining more resources to improve the environment [18]. In line with Van Wingerden and Poell [42], our findings revealed that IHRM can establish a resource-rich working condition through diverse selection, inclusive training, personalized configuration, participatory assessment, and targeted compensation [14], and this, in turn, motivates nurses to engage in job crafting as a form of resource investment [17]. Our results further suggested that additional increased resources and decreased job demands associated with job crafting enable nurses to devote more time and energy to innovative activities that enhance existing healthcare processes, products, and services [22], thus echoing the research of Khan et al. [24]. In this way, our study unveils the theoretical foundations between IHRM and innovation in the nursing context.

5.1.3. Shared Leadership Moderates the Positive Effects of IHRM on Nurses' Job Crafting and Subsequent Innovative Behavior. As a positive leadership style, our findings shed light on the important role of shared leadership in reinforcing the effectiveness of IHRM on nurses' job crafting and innovative behavior, affirming past research that indicated the synergistic effects of positive leadership styles and HRM practices in response to crisis events [10, 46]. Prior studies have highlighted the advantages of vertical leadership, such as transformational leadership, in fostering innovative behavior among nurses during a pandemic [7], neglecting how horizontal models of shared leadership function. Indeed, despite the tremendous pressure during the crisis, nurses have demonstrated a willingness to craft their job to effectively change how they work and interact with patients to improve the quality of nursing service [4], and this process may be influenced by the initiative and autonomy of nursing staff [8]. As an informal collective leadership pattern characterized by members' proactive involvement, self-management, and mutual leading, shared leadership

emphasizes the sharing of leadership roles among members, such as decision-making, power, and responsibilities [45]. In line with this notion, our results indicated that shared leadership can function as a facilitator that grants nurses greater autonomy and initiative to utilize resources from IHRM to engage in job crafting and innovative behavior [28]. This study not only extends the current understanding of the boundary condition of IHRM but also confirms the reasoning that leadership has the capacity to promote HRM process [48]. Therefore, healthcare organizations should strive to enhance the levels of shared leadership to maximize the benefits of IHRM.

5.2. Implications for Nursing Management. Our research provides several practical implications for HR practitioners and nursing leaders in healthcare organizations. Nurses' innovative behaviors have emerged as a critical issue in recent healthcare research [6] and have been proven to have a positive impact on improvements in the quality and effectiveness of nursing services during a pandemic [7]. To create a supportive environment for innovation among nursing staff, organizations should predominantly concentrate on nurses' vulnerability to stress during a crisis event and provide them with adequate tangible and intangible resources [2, 3]. First, HR practitioners are expected to stimulate nurses' abilities, motivations, and opportunities to innovate by adopting various inclusive practices to increase nurses' stock of resources, reduce their pressure, and leverage their strengths [12]. These HRM policies and practices should include fair employment, flexible work, value appreciation, diverse training, participatory decision-making, decent compensation, and targeted rewards [14]. More importantly, HR practitioners in healthcare should also actively involve nursing staff in these available practices and capitalize on nurses' feedback and opinions to timely adjust HRM practices for their potential innovation benefits [15].

Second, we can understand from this research that job crafting is an essential agentic behavior that has a discernible influence on innovative behavior. Given an array of uncertainties associated with the pandemic, nurses should actively redesign their work to achieve a balance between job demands and resources [19]. Accordingly, nursing managers should create a favorable environment for nurses' job crafting, such as creating autonomous work conditions and avoiding unnecessary interference and monitoring of nurses [25]. By proactively seeking opportunities to craft their job according to talents, interests, and strengths, nurses can acquire valuable resources needed for innovation.

Third, our research revealed that IHRM is more likely to facilitate nurses' job crafting and innovative behavior when nurses perceive higher levels of shared leadership. In the changing medical environment, the complexity of tasks and the urgency of time make it difficult for the traditional vertical leadership style to accomplish work tasks with high-quality [27]. To better adapt to environmental changes, nursing leaders in healthcare organizations should improve the levels of shared leadership. Specifically, team members

should be encouraged to share leadership authority and responsibilities to promote the effective achievement of collective goals [29]. In addition, team members need to learn from each other and try new methods to improve their performance.

5.3. Limitations. Our research has several limitations. First, IHRM, shared leadership, job crafting, and nurses' innovative behavior were all self-reported by the nurses, which would inevitably raise concerns about subjective cognitive bias and social desirability. Although we adopted a time-lagged design to measure the main variables at three-time points during questionnaire distribution to mitigate the CMV and Harman's single-factor test and latent common method factor approach illustrated that this problem was not serious, a single source of data could still have some limitations [50]. Second, this study was conducted in four public hospitals in China. The monocultural and organization-specific context may limit the generalizability and extensibility of our findings. However, the current data do not allow for a direct empirical examination of how contextual factors (e.g., culture, organization, and healthcare systems) might influence the relationships between IHRM and related variables through a comparative design [23]. Third, researchers have demonstrated that time-separated measures can be effective in reducing the potential limitations of cross-sectional data (e.g., CMV and reverse causality [15]). However, the one-month time interval recommended by Podsakoff et al. [50] is insufficient to validate the long-term impact of IHRM on nurses' innovative behavior, which may change as the crisis event continues to progress [16].

5.4. Future Research. We also provide some avenues for future research. First, we investigated the impact of IHRM on nurses' innovative behaviors using individual-level data because prior research indicated that individuals might make differential interpretations of organizational intentions behind HRM practices [12]. However, individuals perceived IHRM could hardly demonstrate the objectivity of HRM practices. Therefore, future research could collect data at both organizational- and individual-level to examine how organization-implemented IHRM can influence nurses' innovation through multilevel analysis. Second, considering the differences between Eastern and Western cultures, individuals may have different understandings of "inclusion" and China's unique culture (e.g., high collectivism) makes people more eager to belong or merge into the group, which may lead to a greater positive impact of IHRM on related outcomes in Chinese culture. Accordingly, we encourage future research to explore the role that cultural factors play in employees' perceptions of IHRM and perform a cross-cultural comparative analysis to generalize our findings. In addition, future research could extend our findings to other healthcare organizations since the innovative requirements and expectations are different for nursing staff under different healthcare systems [7]. Third, it is a feasible direction for future research to expand the present study through longitudinal design to compare the impacts of IHRM on

innovative behavior during a crisis event like a pandemic with the impacts under ordinary situations. In this way, scholars could continue to explore whether IHRM and job crafting can predict changes in nurses' innovative behavior over time. Finally, future studies could examine more extensive mediating variables (e.g., psychological capital, thriving at work, and gratitude) to expand potential theoretical explanations between IHRM and innovative behavior [9]. We also recommend future research to explore other boundary conditions such as proactive personality and servant leadership to extend our findings [2].

6. Conclusion

Promoting nurses' innovative behavior can be an effective way for hospitals to acquire sustainable competitive advantage in today's VUCA (i.e., volatile, uncertain, complex, and ambiguous) medical environments. Based on the COR theory, the current study constructs a moderated-mediation model to explore whether, how, and when IHRM can motivate nurses to be involved in innovative work. We tested our theoretical model through a time-lagged field study and the results showed that IHRM is positively related to job crafting, which in turn promotes nurses' innovative behavior. In addition, we uncover when IHRM has a more pronounced influence on nurses' job crafting and innovative behavior by selecting shared leadership as a boundary condition. We found that the direct linkage between IHRM and job crafting and the indirect effect of IHRM on nurses' innovative behavior through job crafting is significant and positive only when the levels of shared leadership are high rather than low. To conclude, our research indicates that IHRM and shared leadership style are two collaborative approaches to facilitating nurses' job crafting and subsequent innovative behavior during crisis events. As such, hospitals and nursing facilities may improve the level of job crafting by adopting IHRM policies and practices that value the personalized values and demands of nurses and enhancing perceived shared leadership that underscores collective learning, mutual support, and member-member exchange, thereby fostering the innovation of nurses.

Data Availability

The data used to support the findings of this study are available from the corresponding author upon reasonable request.

Conflicts of Interest

The authors declare that they have no known conflicts of interest. They also declare that they agree with the content of this manuscript.

Aims and Objectives. The objective of this study was to examine the impact of authentic leadership and conscientiousness on the voice behaviour exhibited by nurses. *Background.* Clinical nurses, being integral members of the medical system and actively engaged with patients and their families, possess significant influence in addressing various work-related issues and contribute significantly to the advancement of clinical services and the overall stability of hospitals within the nursing team. Consequently, it is imperative to prioritize the consideration of nurses' recommendations in order to identify the factors that can effectively enhance their enthusiasm in vocalizing their concerns. *Design.* Data in this cross-sectional descriptive study were collected from March 2021 to August 2021 by the online survey method. *Methods.* A total of 679 Chinese nurses were surveyed with a Chinese Big Five Personality Inventory Brief Scale, an Authentic Leadership Scale, and a Voice Behaviour Scale. Because the data were normally distributed in our study, Pearson's correlation coefficient (r) was used to conduct the correlation analysis of the study variables. The structural equation model was used to examine the mediating role of conscientiousness. *Results.* The results showed that the influencing factors of nurses' voice behavior were education background, employment mode, nursing seniority, and monthly income ($p < 0.05$). In addition, authentic leadership, conscientiousness, and voice behaviour were significantly positively correlated (the correlation coefficients are 0.632 and 0.630, respectively, $p < 0.05$). Conscientiousness plays a partial mediating role in authentic leadership. *Conclusion.* Authentic leadership was the key to improving the voice behaviour of nurses; as a mediating mechanism, conscientiousness further explained how authentic leadership promoted the voice behaviour of nurses. The effects of authentic leadership, conscientiousness, and voice behaviour could be used to guide the management of clinical nurses. In particular, the authentic leadership style perceived by nurses and the conscientiousness of nurses would contribute to the generation of voice behaviour.

1. Introduction

In today's complex and rapidly developing medical environment, nurses tend to be the main providers of primary health care services, and the central role of nurses in health care, including their proximity to patients, clinical decision-making roles, health care education, and preventive services [1–3]. Nurses not only have a significant voice in work-related issues but also play a crucial role in advancing clinical services and maintaining hospital stability [4]. In order to promote the development of the organization, the team

hopes that members can actively provide opinions and suggestions, rather than just completing their own work, which needs to mobilize the enthusiasm of subordinates to participate in the day-to-day management of the organization [5–7]. Voice behaviour can be used as one of the ways for members to participate in organizational management, which can not only enhance the protagonist awareness of subordinates but also give full play to their subjective initiative [8].

Recent studies have demonstrated that managers greatly influence employee voice behaviour, as the primary

recipients [9]. Authentic leadership is the concept that managers shape their subordinates' knowledge, attitudes, and behaviours through their genuine qualities and actions in the management process [10]. And the authentic leader focuses on the positive role modelling of honesty, authenticity, and high ethical standards in the development of leader-follower relationships [11]. This type of leadership is characterized by self-awareness, internalized moral perspective, balanced processing of information, and relational transparency, which can affect employees, stimulate employees' authenticity, enhance their trust in their superiors, and thus promote the occurrence of voice behaviour [10].

Therefore, this study proposed the following hypothesis:

Hypotheses 1. Authentic leadership of nurse managers has a direct positive effect on nurses' voice behaviour.

In addition to the influence of some external environment, employees' personal factors, such as personality characteristics, are also a factor affecting their voice behaviour. An academic study by Wechsler has shown that individual personality, as a kind of tendency, can dominate people's behaviour and perception [12]. For example, the introverted personality tends to look for reasons within itself, has a strong introspection, likes to be alone, and avoids more social contact [13]. The personality of the external control type usually believes that the occurrence of things is affected by external factors, and people with this personality prefer to communicate with others [14]. In other words, personality traits, as the expression of the individual's internal character, will have a more important impact on the individual's psychological state and behavioural performance through different attribution methods. This finding is similar to the attribution theory, which holds that individuals have a process of interpretation and judgment of how events or behaviours occur, and these processes will further affect people's subsequent attitudes and behaviours [15–17].

The big five personality model is currently the most widely used personality trait model to make up the personality structure, including neuroticism, conscientiousness, agreeableness, openness, and extraversion [12]. It has been shown to effectively predict individual work behaviour [18]. Relevant literature has shown that different dimensions of big five personality have different predictive effects of employees' voice behaviour. Lepine et al. [6] revealed that the four dimensions of big five personality have a significant relationship with voice behaviour, among which conscientiousness and openness have a positive impact on employees' voice behaviour. In other words, employees with high conscientiousness have stable emotional attachments with the organization, and they tend to show more positive voice behaviours for the organizational interests. Based on the above statements, the following hypothesis is proposed:

Hypotheses 2. Conscientiousness has a direct positive effect on nurses' voice behaviour.

After systematically organizing the research on personality traits and employees' voice behaviour, Yanzhe et al. [19] found that among the big five personality traits,

conscientiousness and extraversion can positively predict employees' voice behaviour. At the same time, some studies also found that the influence of personality traits on voice behaviour mainly acts through motivation, interpersonal relationships, and emotional mechanisms, and also through the personal characteristics and leadership behaviour of leaders [20–22]. Therefore, when nurses are faced with authentic leadership, whether the influence of this type of leadership on their voice behaviour can be changed to a certain extent through the interpretation and influence of different personality traits remains to be explored. Thus, the following hypotheses were developed:

Hypotheses 3. Conscientiousness plays a mediating role between authentic leadership and voice behaviour.

Understanding the ways in which the authenticity of nurse leaders could promote nurses' voice behaviour is important. In this essence, in this study, we developed a conceptual model relating authentic leadership of nurse managers to nurses' voice behaviour. In this model, it is anticipated that conscientiousness would mediate the link between the authentic leadership of nurse managers and nurses' voice behaviour.

To sum up, this study was designed to (1) investigate the relationship between the authentic leadership of nurse managers and nurses' voice behaviours, (2) examine the relationship between conscientiousness of nurse and nurses' voice behaviour, and (3) explore the mediating role of nurses' conscientiousness in the relationship between nurse managers' authentic leadership and nurses' voice behaviour.

2. Methods

2.1. Study Design and Sample. A cross-sectional study was adopted, and the method of convenience sampling was used in this study. Participants in this study were nurses from five general hospitals in north China. Data collection was conducted from March 2021 to August 2021.

A standardized questionnaire will be made and distributed to our subjects (clinical nurses). Before the investigation, researchers were trained in a unified manner. And all of the investigators used a unified guidance language to avoid leading statements. Before the survey, participants were informed of the purpose and significance of the survey and the precautions during the survey. All participants were anonymous and voluntary. The effectiveness of the questionnaire was ensured through an on-site audit and the audit on the same day. Researchers conducted a one-to-one survey of nurses. During the survey, participants were asked to think of a specific leader while filling out questionnaires.

Because this study is descriptive and the primary outcome is a continuous variable, the sample size was estimated using the following formula [23]:

$$n = \left(\frac{U_{\alpha/2}\sigma}{\delta} \right)^2 = \left(\frac{1.96 \times 1.80}{2} \right)^2 = 553.19 \approx 554 \text{ nurses,} \quad (1)$$

where n indicates the required sample size, $U_{\alpha/2}$ is the standardized normal deviation corresponding to $\alpha = 0.05$ and 95% confidence level ($U_{\alpha/2} = 1.96$, for two-tailed), σ

indicates the expected value of standard deviation in the population ($\sigma = 1.80$ from the pilot study), and δ indicates the acceptable margin of error for the mean ($\delta = 0.2$, based on the pilot study). To consider the nonresponse rate and uncompleted questionnaires, 700 nurses were invited to take part in the study.

The inclusion criteria were as follows: (a) licensed staff nurses; (b) nurses on duty during the study period; and (c) nurses had no less than 1 years of tenure in their current hospital. And the exclusion criteria were the rotation of nurses, or those who were unable to participate in the study due to vacation, leave, and illness. Of the 700 questionnaires returned, 21 were invalid and excluded from the analysis. Thus, the final sample size for this study was 679 with an effective rate of 97%.

2.2. Instruments

2.2.1. Sociodemographic Data Questionnaire for Clinical Nurses. After reviewing the literature, we designed the sociodemographic data questionnaire for clinical nurses based on the needs of this study, including their gender, age, marital status, education, hiring method, nursing tenure, and monthly income.

And this study also used three standardized scales to collect the data. And the scales used in this study were professionally translated into Chinese. All items were measured on a 5-point Likert scale.

2.2.2. Authentic Leadership. This study adopts the authentic leadership questionnaire developed by Walumbwa et al. [24], which tests the sample data of Chinese enterprises in the development process of the questionnaire. And this is the most widely used survey scale on authentic leadership at present. The scale includes 4 dimensions, including 4 items of self-awareness, 5 items of relational transparency, 4 items of internalized moral, and 3 items of balanced processing, for a total of 16 items. The Cronbach α value of the scale was 0.95.

2.2.3. Conscientiousness. This study adopts the Chinese Big Five Personality Inventory brief version (CBF-PI-B) compiled by Mengcheng Wang and Xintong et al. on the basis of the China Big Five Personality Questionnaire [25], including five dimensions: neurotic, conscientiousness, agreeableness, openness, and extroversion. There are 8 questions for each personality trait. The Cronbach α value of the scale was 0.93. And this study had selected questions about conscientiousness.

2.2.4. Voice Behaviour. The 10-item Chinese version of the voice behaviour scale was developed by Liang et al. [26]. The tool consisted of two dimensions: promotive voice and prohibitive voice. The Cronbach α value of the scale was 0.93.

2.3. Pilot Study. To ensure the questionnaire was understandable and clear, we did a pilot study. And in the pilot study, we also estimated a preliminary mean of the outcome

variables to estimate the sample size needed. We recruited 30 nurses from the participating hospitals, in the pilot study, who were then excluded from the study sample. The questionnaire took approximately 5–10 min to complete, and piloted nurses assured that the items were understandable and clear.

2.4. Ethical Consideration. First, the informed consent of hospital leaders was obtained before the questionnaire was distributed. The purpose and significance of the study were explained in detail to the participants, and informed consent was obtained. Second, we made sure that participants' responses were used only for the study and that they could opt out at any time. In addition, the study was conducted anonymously, did not include unethical practices or human clinical trials, and did not have any adverse effects on the physical or mental health of the participants. In the end, the Ethics Committee of Henan University approved the study (ID: HUSOM2022-238).

2.5. Statistical Analysis. Data were analyzed using SPSS 24.0 (Chicago, IL, USA) and AMOS 24.0 (IBM Corp.). The demographic characteristics of the participants were described using frequencies and percentages. The three main study variables (i.e., authentic leadership, conscientiousness, and voice behaviour) were described using means and standard deviations. An independent sample *t*-test or one-way analysis of variance (ANOVA) was used to identify differences in the study variable according to demographic characteristics. Pearson's correlation analysis was used to determine the correlation between the major study variables.

A two-step structural equation modeling (SEM) was used to test the hypotheses [27]. According to the recommendation of Hu and Bentler [28], the following goodness-of-fit statistics were used to evaluate the fit degree of model and data: the chi-square/degrees of freedom ratio (χ^2/df), the root-mean-square error of approximation (RMSEA), goodness of fit (GFI), adjusted goodness of fit (AGFI), Tucker–Lewis index (TLI), comparative fit index (CFI), and root-mean-square residuals (RMR). A lower χ^2/df value means better model fitting. Lower RMSEA also suggests better model fitting. GFI, TLI, CFI, AGFI, and NFI range from 0 to 1, with values closer to 1 indicating better fit. Finally, we used 5,000 samples for bootstrap resampling and a 95% confidence interval (CI) to test the direct and indirect effects between conscientiousness, authentic leadership, and voice behavior [29].

3. Results

3.1. The General Characteristics of the Subject. A total of 679 participants participated in the study. The participants were predominantly female (84.7%) and married (72.5%). Of the respondents, more than half had an age less than 40 years (74.3%) and had obtained a Bachelor's degree (69.7%). Regarding working experience, most study participants spent less than 10 years in the nursing profession. Moreover, Table 1 displays the differences in the basic characteristics of

TABLE 1: Participants' basic characteristics and differences in authentic leadership, conscientiousness, and voice behaviour ($n = 679$).

^aOthers: divorced and widowed. [‡]*t*-test for the independent group. [†]One-way analysis of variance. * $P < 0.05$; ** $P < 0.01$.

the participants in authentic leadership, Conscientiousness, and Voice behaviour. Nurse's perception of authentic leadership was significantly different in different gender, age, education, nursing tenure and monthly income. In terms of conscientiousness, there were significant differences in age, hiring method, and nursing tenure. Similarly, different education, hiring method, nursing tenure, and monthly income also significantly affected the score of voice behaviour (Table 1).

3.2. The Correlation of Variables. Pearson's correlation coefficient showed that there was a moderately positive correlation between authentic leadership and conscientiousness ($r = 0.513$, $P < 0.01$) and voice behaviour ($r = 0.632$, $P < 0.01$). Similarly, this relationship also existed between conscientiousness and voice behaviour ($r = 0.630$, $P < 0.01$; Table 2).

3.3. Path Analysis of Each Variable. In order to explore the relationship between conscientiousness, authentic leadership, and voice behaviour of clinical nurses, voice behaviour was taken as the dependent variable, authentic leadership as the independent variable, and conscientiousness as the mediating variable. Based on the previous studies, a corresponding structural equation model was constructed, and

TABLE 2: Correlation between authentic leadership, conscientiousness and voice behaviour.

Variables	1 <i>r</i> (<i>P</i>)	2	3
(1) Authentic leadership	1		
(2) Conscientiousness	0.513**	1	
(3) Voice behaviour	0.632**	0.630**	1

** $P < 0.01$.

the Bootstrap method was used for validation analysis. The model-fitting index was used to determine the fitness degree between the results and the data. The results showed that the model fitted well with the data (Table 3).

We conducted a path analysis to estimate the direct and indirect effects of both authentic leadership and conscientiousness on voice behaviour (Figure 1). The results revealed that authentic leadership has positive and significant direct effects on voice behaviour ($\beta = 0.396$, $P < 0.001$) and conscientiousness ($\beta = 0.565$, $P < 0.001$). Similarly, conscientiousness has a positive effect on voice behaviour ($\beta = 0.521$, $P < 0.001$). When conscientiousness was added as the mediating variable, the effect size of authentic leadership on voice behaviour increased by 0.294, and the total effect size reached 0.691. Therefore, conscientiousness has a partial mediating effect between authentic leadership and voice behaviour (Table 4).

4. Discussion

This study was designed to determine the effect of authentic leadership on nurses' voice behaviour at work. And the structural equation model was used to confirm whether

nurses' conscientiousness played a mediating role in the effect of authentic leadership on voice behaviour. The general characteristics show that 84.7% of the nurses that participated in this study were female, which is in line with previous studies performed in China [9].

In this study, a nurse's age, education, hiring method, length of clinical work experience, and monthly income are positively related to their voice behaviour. A previous study [30] found that the length of clinical working time and monthly income are important factors affecting nurses' voice behaviour, which was consistent with our research results. Our study found that clinical nurses who have worked for more than 15 years and earned more than 10,000 yuan per month scored higher in voice behaviour. This is consistent with the investigation of Zhao et al. [30]. Nurses who have worked for a short period of time are worried about their lack of professional knowledge and clinical experience, lack of mutual trust with leaders and colleagues, and fear of putting forward inappropriate opinions or suggestions, so nurses who have worked for a long time are more familiar with the work of the department and more willing to talk [31, 32]. In terms of education level, nurses with an associate's degree or below had more active voice behaviour. It may be because most of the highly educated nurses are new graduates. This was consistent with Wesche's research results which identified how newcomers will often choose silence to fit in (organizational socialization) rather than suggest changes which could risk relationships [33].

In addition, in this study, authentic leadership was positively correlated with nurses' voice behaviour, and authentic leadership had a positive and direct predictive effect on nurses' voice behaviour ($\beta = 0.396$, $P < 0.001$). Voice aims at challenging the position of organizations, so it is risky [34]. Leaders usually regard the voices as threats, so they react negatively to outspoken employees [35]. Considering the risk of speaking, employees would carefully assess their social background before speaking [36]. If employees' voices are regarded as complaints or annoyances by leaders, they may face negative comments and be assigned to dissatisfying jobs [37]. At this time, employees would give up the voice to avoid adverse consequences and regard the voice as dangerous behaviour [38]. Authentic leaders know their own strengths and weaknesses and will be aware of their own limitations in making decisions and solving problems, so they are more likely to accept employees' ideas and opinions and even encourage employees to challenge the tradition. Furthermore, the authentic leader is committed to the establishment of a transparent relationship within the organization, which requires managers to balance the diversity and discrepancy of information. These acts will enhance subordinate trust in leadership, let them give up concerns, and allow them to express their true thoughts and feelings [39]. This shows that under the authentic leadership of the head nurse, the nurses and the head nurse trust each other and get closer to each other. When there is any problem in the work, the nurses will put the interests of the collective in the first place.

The results of this study showed that nurses' conscientiousness was a positive predictor of voice behaviour ($\beta = 0.521$, $P < 0.001$), indicating that the higher the conscientiousness of nurses, the more positive their voice behaviour that is consistent with previous research [6]. Voice behaviour is the behaviour that employees take the initiative to make suggestions to leaders or point out the existing

mistakes of the organization in order to improve the organizational effectiveness [40]. However, people with conscientiousness are generally more careful and prudent [41]. At the same time, people with high conscientiousness scores tend to be more goal-oriented [42]. In order to improve the organizational environment, they think they have a responsibility to contribute to the organization and are willing to have an active dialogue with colleagues and leaders [43]. They express their views patiently until they were understood [44].

The structural equation model analysis of this study showed that the direct predictive effect of head nurses' authentic leadership on nurses' voice behaviour was 0.396 ($P < 0.001$), the total effect of head nurses' authentic leadership on nurses' voice behaviour was 0.691 ($P < 0.001$) after adding conscientiousness personality, and conscientiousness had a partial mediating effect in the effect of head nurses' authentic leadership on nurses' voice behaviour. In other words, when nurses perceive the authentic leadership, their personality will affect their voice behaviour by their self-perception. This finding is in line with attribution theory, which holds that an individual's personality influences subsequent behaviour by judging and interpreting the behaviour of others or the external environment [15, 16]. Voice behaviour is aimed at promoting mutual cooperation, expressing employees' views and opinions on the organization. When the head nurse adopts an authentic leadership, nurses can feel the trust, care, and motivation from their superiors, so that they are more willing to integrate the development goals of the organization into their personal values and ideals [45]. Nurses with conscientious personality are cautious and responsible. Based on these characteristics, nurses with conscientiousness will not avoid talking about the problems found in their clinical work. Moreover, nurses with conscientiousness will be more likely to perceive and amplify the authenticity of the leaders [46], so as to promote the relationship between authentic leadership and voice behaviour.

5. Limitation

First of all, convenience sampling method was adopted in this study, and only a few hospitals in Henan Province were selected, with regional limitations, the generality and popularization of the conclusions may be limited. Second, the data obtained in this study were based on self-report. Although all participants had obtained anonymity and confidentiality, they still could not completely avoid reaction bias and social desirability bias could have affected the reporting of this behaviour. Finally, this was a cross-sectional survey, so the observed association should not be considered causal, and further research is required to explore the causal relationship.

6. Conclusion

This study explored the influence of authentic leadership and conscientiousness on the voice behaviour of nurses through the SEM. The results showed that authentic leadership and

conscientiousness had a direct impact on voice behaviour. Conscientiousness partially mediated the relationship between authentic leadership and voice behaviour. Therefore, the nursing managers in the medical institutions, especially the head nurses, should actively develop an authentic leadership style. At the same time, training the conscientiousness of nurses can effectively promote voice behaviour. Since this study is a cross-sectional study, a longitudinal design is needed in the future to verify the validity of the findings.

7. Implication for Nurses' Management

Our findings provide many practical implications for hospital management. First of all, in view of the role of authentic leadership in promoting voice behaviour, the managers in medical institutions, especially the managers of nurses such as the head nurses, should actively change their leadership behaviour patterns and cultivate authentic leadership styles. Managers should share information, be open and honest in their dealings with employees, seek feedback from employees, involve them in decision-making, and demonstrate their ethical standards. Secondly, this study found that conscientiousness can play a partial mediating role between authentic leadership and voice behaviour, which suggests that managers should pay full attention to the fact that employees have individual differences. In their daily work, managers should identify employees' personality characteristics and formulate differentiated coping strategies in management. And managers also should pay attention to the selection and appointment of conscientious nurses. In order to arouse the enthusiasm of nurses, nurse managers can enhance their sense of responsibility by means of material, promotion, and modeling.

Data Availability

The [sav] data used to support the findings of this study are available from the corresponding author upon request.

Additional Points

Patient or Public Contribution. Participants contributed to this study by completing a questionnaire that included

sociodemographic data, authentic leadership, conscientiousness, and voice behaviour.

Conflicts of Interest

The authors declare that there are no conflicts of interest.

Authors' Contributions

Yujun Fan wrote the original draft, coordinated the project, and analyzed the data. Chaoran Chen supervised, reviewed, and edited the study. Xiaoyuan Qu and Wuxing Zhang proposed the methodology and were responsible for consultancy. Zhimin Tao reviewed and edited this study.

Acknowledgments

The authors particularly acknowledge the staff who helped collect dates and coordinate this survey and all participants who took part in this survey.

Introduction. Rural nursing careers offer a multitude of benefits for individuals. Despite this, there continues to be a growing deficit in the number of nurses choosing to practice in rural areas. As the first 12–18 months of a nursing career are fundamental in shaping career location decisions, it is important to explore factors that influence early career nurses' employment decisions. *Methods.* A phenomenological study was undertaken to explore early career nurses' experiences during their first year of rural practice and describe how the nurses' experiences influenced their decision to remain in rural employment. Data were collected via semistructured interviews and underwent inductive thematic analysis. *Results.* Seven early career nurses practicing in rural locations were interviewed and described several influences on their career location decisions, particularly related to whether they would stay in or leave their rural employer. The themes derived from the nurses' stories included the effect of their vulnerability entering a new workplace, the importance of connection to person, place, and profession and the nuances of rural nursing rhythms. These had implications on their employment decisions. *Conclusion.* This research demonstrates the distinct form of nursing practice that occurs in rural areas which was experienced by the early career nurses as a breadth of skills, volume of presentations, and continuity of care. The nurses described the importance of establishing connections to person, place, and their profession. These connections can support nurses through a period of vulnerability entering a new workplace.

1. Introduction

Rural nursing careers can provide a multitude of benefits for individuals, including higher wages, providing a sense of belonging, and allowing nurses to work to their full scope and develop generalist nursing skills [1]. Despite these benefits, there remains a significant shortage of nurses working in rural areas, which is expected to continue to grow [2, 3] despite an increasing number of graduates [4]. The rural nurse shortage has led to significant efforts to conceptualise and explore ways to retain staff in these locations. The first two years of a nurse's career are important in this endeavour, as the first 12–18 months of employment has been reported as the period in which a decision is made to stay or leave. To date, research that has explored the experiences of early career nurses has largely been conducted in metropolitan settings [5–9]. Rural nurses have a distinct

scope of practice which includes functioning as an advanced generalist, being intricately linked with community, and holding significant responsibilities in delivering health services [10, 11]. It is therefore important to conduct research that considers practice from the unique perspective of rural nurses. There has been research conducted on recruitment and retention specifically in rural areas, but this has not included early career nurses as a sample group [2].

This qualitative study focuses on the experiences of early career nurses practicing in rural areas in New South Wales (NSW), Australia, and describes the influences on their retention. Early career nurses in this context refer to nurses registered with the Australian Nursing and Midwifery Board, which requires them to have completed a three-year undergraduate degree consisting of theoretical and practice-based education. Many early career nurses employed in the NSW public health system are enrolled into a program that

focuses on the first year of transition to practice. Programs similar to this have been evaluated previously and found to be highly variable in terms of content and success [12]. There is also evidence that the effect of factors such as ward culture and experiencing a sense of social inclusion influence the retention of junior nurses, although this remains largely underexplored in research [13–15]. The purpose of undertaking this research was therefore to contribute to an increased understanding of the influences on early career nurses' employment decisions in rural areas.

To do this, a descriptive phenomenological design was used to privilege the experiences of the early career nurses, understanding they are unique and highly impactful on their employment decisions. Descriptive phenomenology (versus interpretive phenomenology) was chosen to guide this research as it requires the researcher to use bracketing and develop an outlook of the phenomena from which they are distanced [16]. The researchers felt that this reflected the nature of the inquiry related to a phenomenon from which they are distanced (in relation to geography, discipline, and career stage) and seeking to explore broadly. This approach is appropriate for addressing the study aims as it recognises that career decision-making is complex and requires an open exploration of the reasons nurses leave their employment, as well as those that influence them to stay [17].

1.1. Aims

- (1) To explore early career nurses' experiences during their first year of rural practice.
- (2) To describe how the nurses' experiences influenced their decision to remain in rural employment.

2. Methods

This paper presents results from a qualitative analysis of interviews undertaken as part of a larger, mixed methods research project. Descriptive phenomenology was used as the aims were focused on exploring the subjective experience of early career nurses. Using this methodological approach, the researchers sought to explore how the first year of practice (the phenomenon of interest) was viewed by the individual. Ontologically and epistemologically, this research adopted a lifeworld approach based on the work of Husserl [18]. This view negotiates between subjectivism and objectivism and focuses on the relationship between participants and the world. "The lifeworld is the lived and experienced world and thus it is something more than the world itself, and more than the subject itself" [19]. The researchers involved in collecting and analysing data were guided by the methodological principles of descriptive phenomenology suggested by Sundler et al. [20], emphasising openness, questioning preunderstanding, and adopting a reflective attitude. Bracketing was conducted within the stage of openness, whereby the researchers identified and set aside their assumptions and pre-suppositions in order to be open to the data [16]. This research is reported in line with the consolidated criteria for reporting qualitative research (COREQ) [21] to enhance

transparency and trustworthiness of the research process and results [22]. For the purpose of this study and the discussion in this paper, rural refers to locations rated 1–4 (Inner Regional to Very Remote) using the Australian Statistical Geography Standard (ASGS) Remoteness Structure [23].

2.1. Participants and Data Collection. Participants were purposively recruited from orientation sessions for cohorts of early career nurses (first year of practice) commencing in either of two rural local health districts in New South Wales, Australia, in 2019 and 2020. Recruitment was conducted 10–12 months from when the nurses commenced working in their role to capture them at a stage where they had experience of the phenomenon (working as an early career nurse) and were still located in their rural site (the early career program is for 12 months, and many nurses relocate after this period). The total size of the cohort was 175 nurses who were entering the workforce having become a registered nurse within the previous 6 months. Prospective participants were able to identify interest in being interviewed by noting their contact details at the end of a survey that was administered during orientation sessions as part of the larger research project. Coercion bias was mitigated by using a research team who were not known to the nurses and employed by a separate organisation. Outcomes of the research were not tied to the nurses' employment. Nurses who left their contact details were contacted by a researcher (EG or RB) to discuss the project and then emailed the information and consent sheets. After one week, the researcher invited the participant to an interview, arranged at a time of convenience for the participant.

Interviews were conducted by two members of the research team (EG and RB) and were completed virtually using an online videoconferencing platform. Interviews took between 27 and 46 minutes (with a mean time of 36 minutes). A semistructured interview guide was used to conduct the interviews (Table 1). The interview guide was developed based on the information required to answer the research question and concepts from the literature thought to affect the experiences of early career nurses (i.e., social connections, career ambitions, and placement locations). One question was added to the interview guide following the second interview as the participant raised the impact of COVID-19 as being significant for their experience as a nurse, so this was asked of subsequent participants. Data saturation was not used as guidance for participant numbers, taking the view of Braun and Clarke [24] that meaning is generated through the analysis rather than reaching a point of saturation. The sample size was therefore guided by how many nurses opted in to the research and a sample of seven is sufficient considering the phenomenological approach [25, 26]. For all interviews, only the researcher and the participant were present and each interview was video-recorded and then transcribed verbatim. Written informed consent was obtained from each participant prior to the interview, and no participants withdrew after providing consent. Each interviewee was offered to be sent a copy of the interview

transcript to review and make any comments, explanations, or amendments; however, none opted to do so.

2.2. Data Analysis. Thematic analysis of interview transcripts was undertaken using a descriptive phenomenological approach. Guidance from the work of Sundler et al. [20] was used, whereby the process of analysis incorporates visiting the interview transcripts as a whole and as individual descriptions of the phenomena, with the researchers moving between closeness and distance from the data. Data analysis was conducted by three members of the research team (RB, LK, and EG). The three researchers who undertook data analysis identify as women and are from the disciplinary backgrounds of social work, occupational therapy, and nursing, respectively. The three researchers all work at a regional university and are involved in programs that focus on the recruitment and retention of rural health professionals. As health professionals, they have all practised in rural Australia for >10 years.

During analysis, each researcher considered their pre-understanding of the phenomena and conducted open-minded reading (bracketing) before exploring the meanings embedded in each interview. The process of data analysis was highly reflective, and the team met frequently throughout the process of analysis to discuss and reflect on results. Thematic analysis was inductive, and the themes presented in the results of the research were data-driven. To reflect the importance of the individual story for understanding the results of the research, each participant was given a pseudonym name and their story presented as part of the results. This acknowledges the different journeys and experiences of each person. Quotations used in the results section aim to give voice to each participant and are attributed to the person from whom the words came.

2.3. Ethical Approval. This research was granted human research ethics approval by the Greater Western Human Research Ethics Committee, approval number 2019/ETH00108.

3. Results

3.1. Summary of Participants. Seven early career nurses, all of whom identified as women and had been working as a registered nurse for 10–12 months, opted to be interviewed for this research. A summary of the participants and their stories is presented in Table 2.

3.2. Thematic Analysis. A descriptive phenomenological approach was undertaken to analyse the data, and themes were inductively developed using the experiences of the participants. There were three main themes identified in the data that related to the individual experiences of the participants and told a story about the overall influences on the nurses as they entered professional practice and subsequently made decisions about employment. The themes included “The effect of vulnerability during

a period of transition,” “Connection to person, place, and profession,” and “Nuances of rural nursing rhythms” and are presented below with reference to the experiences of the individuals.

3.3. The Effect of Vulnerability during a Period of Transition.

The theme “Effect of vulnerability during a period of transition” demonstrates the experiences of the early career nurses joining a new workplace and, in many cases, a new profession. During this transition time, many of the nurses spoke of their feelings of vulnerability, and how this resulted in their experiences having a heightened effect on them. Riley’s experience demonstrated this

“... it was a big shock to my system. My previous job was 9 to 3 Monday to Friday and now I’m full-time on a rotating roster. So trying to balance social life and adulthood with work especially having to drive . . .” (Riley)

Similarly, Jesse felt that the transition had a significant effect on her familial and social connections.

“I think for the first couple of months I didn’t see anyone or talk to anyone. I was just too tired, and too overwhelmed. And there was so much new knowledge coming at me all the time that I—it was just—it was a good effort if I could do the dishes on that day, or make my bed. There was—it was hard. Now it’s a little bit better.” (Jesse)

The vulnerability felt by the nurses resulted in their initial experiences being strongly influential on their happiness and decisions to remain or leave. Sam described receiving a warning when she first arrived in the new town and how this affected her entire experience.

“So, when I started, I remember the first day, my NUM (nurse unit manager) came to pick me up . . . and the first thing she said to me that really surprised me was, she said we’ve got a lot of strong characters here and I was like okay and I didn’t know what it means” (Sam)

For Sam, this conversation put her on alert for conflict and affected the way she approached the role. In contrast, some participants spoke to the value of a supportive, welcoming, and positive atmosphere within the team where skill development, feedback, and teamwork were modelled by existing team members. Examples of this included being supernumerary for two weeks, monthly debriefing session, and creating and extending their social connection to the community, as was demonstrated by Alex.

“In the country hospitals, the senior nurses are really lovely, and they’ll always back you up, and then if you’re not unsure what’s happening with a patient, they’ll lead you and they’ll tell you where you need to look, and what information you can investigate or research or do more studying. So, you’ll feel like a real nurse then. . .” (Alex)

TABLE 1: Semistructured interview guide.

Question	Additional questions to probe for more information
1 Tell me about why you chose to become a nurse? What kind of nurse do you see yourself as?	(i) Probing for life experience or influences on career choice (ii) Looking for an understanding of if/how they identify themselves as rural or working within a rural context
2 Tell me about how you decided to come and do the transition to professional practice in this local health district?	(i) Probe for other experiences of living/working in rural areas before study, during study etc. (ii) Feelings of connection to the area
3 During your undergraduate studies for nursing, did you do any clinical placements in a rural/regional/remote area?	(i) Tell me about your experience/s
4 Did these experiences affect your decision to take a position in this local health district?	(i) What influenced your decision-making?
5 What were the best and most challenging parts of being a new graduate?	(i) What do you think are the best parts about being a new graduate? (ii) Let's talk about the most challenging parts of being a new graduate. . .
6 Tell me about your experience of COVID-19 and the effect it has had on you (if any) personally and professionally?	(i) Looking at the effects of the pandemic on both social and professional experiences (ii) Has your perspective of your future career as a nurse changed due to COVID?
7 Tell me about the social, nonwork side of things over the past year while you have been doing the program?	(i) Social and community connections, keeping in touch with family and friends, feeling a sense of belonging
8 What are the things that would/have made you want to stay?	
9 What do you think the future holds for you career-wise?	(i) Looking to see what opportunities they perceive are available, factors that affect decision to stay or leave and where they will be seeking future employment (ii) What's next for you?

TABLE 2: Summary of participants and their stories.

Summary of participants' experiences
<p><i>Sam's story:</i></p> <p>(i) Applied for new graduate program in rural area as heard positive stories from other student nurses about rural nursing, no family living in the area</p> <p>(ii) Experienced "negative" work culture and limited clinical support. Did not experience a sense of belonging, inclusion, and connection at work and in the community</p> <p>Outcome: relocated from the area where the new graduate program was completed and secured employment in an outer regional area</p>
<p><i>Alex's story:</i></p> <p>(i) Applied for new graduate program in rural area for experience and employment prospects, no family living in the rural area</p> <p>(ii) Felt supported by senior nurses and team. Included and connected to people outside of work</p> <p>Outcome: relocated back to major city area after completing the new graduate year to be with family</p>
<p><i>Darcy's story:</i></p> <p>(i) Applied for new graduate program in rural area as previously worked as an enrolled nurse there. Strong connection to the rural area and rural people. Family living in the area</p> <p>(ii) Some feelings of being overwhelmed by the clinical work as a new graduate. Felt welcomed into the team and well supported</p> <p>Outcome: despite an interest in relocating to work in a larger hospital, decided to stay in the rural area and consider relocating after 5 to 10 years</p>
<p><i>Charlie's story:</i></p> <p>(i) Applied for new graduate program in rural area as already residing there. Strong connection to the rural area and rural people. Family living in the area</p> <p>(ii) Some challenges related to the COVID impact on work, including reduced access to study days and professional development. Felt welcomed into the team and well supported</p> <p>Outcome: stayed in the rural area after new graduate year as felt familiar with the service and seeking job security</p>
<p><i>Kelly's story:</i></p> <p>(i) Applied for new graduate program as worked as an enrolled nurse there and felt supported by management. Strong connection to the area and rural people. Family living in the area</p> <p>(ii) Some challenges related to the COVID impact on work, such as access to professional development. Felt supported at the service, attracted to the familiarity and flexibility of the service</p> <p>Outcome: stayed working in the rural area after new graduate year for career and professional development opportunities, support from colleagues and the flexibility with family commitments</p>
<p><i>Riley's story:</i></p> <p>(i) Applied for new graduate year in Sydney and Melbourne as intended to move to city. Accepted new graduate offer in a rural area after being unsuccessful with first preference</p> <p>(ii) Some challenges related to balancing shift work and social life. Felt welcome and supported, developed connections with colleagues and community. Enjoyed learning exposure, opportunity to be in charge</p> <p>Outcome: stayed in the rural area after the new graduate year for financial, social, and lifestyle reasons</p>
<p><i>Jesse's story:</i></p> <p>(i) Applied for new graduate year in rural area as already residing there and hesitant to leave, family close by, strong connection to rural areas and people</p> <p>(ii) Some challenges related to the COVID impact on work, adjusting to full time work and making connections with people due to age. Felt a sense of belonging and experienced a positive culture at work</p> <p>Outcome: planned to stay in the rural area after new graduate year for support, connection with colleagues and community</p>

The impact of a transition period of vulnerability for many of the nurses meant that their initial introduction into the rural workplace had lasting and significant effects. The initial positive or negative experiences influenced their career choices. One exemplification of this was described by Sam who had applied for a rural nursing position and was excited to commence a rural career. The negative work culture and limited support experienced by Sam led her to relocate to a different rural facility at the end of her one-year contract.

The research participants did describe some protective factors that assisted them during their period of vulnerability and negated some of the effects of their experiences. These were described as having previously undertaken shift work, having lived locally, or having skills that were transferable to

this new environment. An example of this was shared by Kelly.

"I know like a lot of people say like time management's really difficult in your first year out, but, for me, because I had already been an enrolled nurse and I think, you know, I'm a mum of, you know, 4 kids and so I feel like, for me, my time management skills are pretty spot on because I've had to be able to study and be able to work."
(Kelly)

In summary, this theme demonstrates the increased vulnerability of early career nurses in relation to personal and professional challenges, the influence this has in terms of heightening the effect of positive and negative experiences,

and some of the skills and experiences that can potentially mitigate some of these effects.

3.4. Connection to Person, Place, and Profession. The early career nurses who participated in this research felt their experiences had been moulded through the connections they made to people, place, and the profession. This was largely spoken of in the context of working in a rural workplace. Feelings of belonging in their new environment were important to the nurses. This was shown by Kelly who described,

“... we know a lot about each other, we share a lot of information about ourselves and our family because we work really long hours [together]... these people that we work with become your extended family, and that’s definitely a rural [hospital].” (Kelly)

Many of the participants described the positive effect of colleagues being open and happy to share knowledge, creating regular social catch ups either inside or during work hours (i.e., regular lunch outside of the hospital). Other examples were colleagues attending the same Church, organised group nights out, text messaging after work to check in, sharing of food in the staff room, and invitations to colleagues’ homes.

Feelings of belonging were not discussed in the isolated environment of the workplace. Two of the nurses who were established in the rural location prior to their new career felt a sense of belonging that extended into the community. Kelly explained,

“... Most of the other nurses and colleagues I work with know a lot about my family and they will see my children down the street or at the shops and most of them, you know, my children, you know, share a special bond with them as well and – yeah. So that’s probably a really good thing about working rurally...” (Kelly)

Darcy also discussed connection and belonging in relation to the wider rural community,

“...I usually can relate to most people because I’m married to a farmer as well. So a lot of the patients have got farming—are either farmers themselves, or married to farmers, or connections to—like you sort of feel connected more than just one person—on a personal level. You sort of feel like you’re connected I guess locationally as well...” (Darcy)

As a profession, nursing also connected the participants to the community. Darcy described how the nursing uniform connects people “because nearly everyone knows someone that works at the hospital.” Kelly had similar sentiments about the nursing connection to community and spoke about knowing patients as people,

“I like to work in rural areas because I’m in a community where you see these people that we discharge and we see them down the—you know, at the supermarket or we see

them somewhere out and they recognise us and we recognise them and in some ways you follow up with their story... the whole story and their journey that they go through with their health...” (Kelly)

Although feeling connected to the rural community influenced the nurses’ decisions to stay working in this location, feeling disconnected had the opposite outcome. Sam described feeling disconnected which led her to relocate to a different rural town. Reflecting on her experience, Sam explained

“I think it was not culturally, it’s not, it wasn’t, I wasn’t, I didn’t feel like I was part of it. Like after work I had no life and you know, I tried going out exercising and all that kind of stuff, but you know, when the nurses, they don’t involve you in activities...” (Sam)

For Sam, the segregation had significant effects and she got to the point where

“I don’t think I can survive here... you would finish work after a stressful shift and all you need is a friend and you’ve got no one there. There is no one...” (Sam)

This theme demonstrates the nurses’ experiences of connection and how this influenced their career decisions. These findings show that nurse retention is influenced by factors not solely related to their learning and clinical practice but is connected with their personal embeddedness in a community. Riley explained

“... You just feel so loved and supported which is going to be hard to say goodbye to if I do decide to go onto somewhere else.” (Riley)

3.5. Nuances of Rural Nursing Rhythms. The participants described their experiences of rural nursing and discussed this type of work as being a distinct form of practice. They highlighted that, in rural areas, patients are often significant people in their community and/or personal life. Participants described the rhythm of rural practice as being unique as they often followed someone through their entire admission, working across specialties from emergency to aged care. Kelly explained

“I really enjoy seeing someone’s life—I suppose—like the whole story and their journey that they go through with their health and being able to try to help them in those ways.” (Kelly)

The practice scope of rural nursing and this continuity across a person’s health journey was also described as facilitating greater rapport and understanding of a person’s individual health and circumstances. Sam even described one experience of closeness with a patient

“Being there for a patient like that when there is no family member, you know, holding his hand, just telling them it’s okay I’m here with you. As a graduate nurse, that was the

beauty I had there was, you know, you do everything. . .” (Sam)

Rural nursing rhythms were also described in relation to the volume of emergency presentations which, in some sites, were infrequent but challenging due to the variety and unpredictability. This required a unique skill set particularly when working without other health professionals onsite in a geographically isolated area. This perspective contributed to the narrative of rural nursing as a distinct form of practice requiring a broad set of skills.

In addition to the professional considerations of a rural nursing career, Jesse described the challenges it could pose when negotiating shift work and personal commitments,

“... I don't feel I have enough time off to go and see my family. It's a weekend trip if I go, it's 3 hours, or 5 hours depending on which I go. And so I think yeah having 2 days off after you finish on an afternoon is—it's too hard to make an effort to go to—to go either—either place. So I haven't seen them in a long time.” (Jesse)

These professional considerations therefore also interact with connections and, in this instance, affected the nurse's access to support networks. Although this was a complication for Jesse, for Alex who had also newly moved to the area, the rural rhythm was one of contentment.

“... you have your own peace and quiet, and then if you want that social life, you can have social life, you can go to see other people, or you can organise something” (Alex)

This theme demonstrates the early career nurses' description of rural nursing rhythms as being a distinct form of practice, allowing for continuity of care, and being considered in the context of geography. The nurses reflected positively on their clinical experiences, and there were no instances of the nurses reporting an intention to leave based on clinical experiences.

4. Discussion

Early career nurses have been recognised as a cohort of nurses who can be highly mobile due to a range of personal and professional factors [27]. This research sought to explore the experiences of early career nurses in rural areas to determine the influences on the likelihood they would be retained in their rural workplace. It was identified that during the period of transition into the workplace, these nurses were vulnerable to the effects of their environment, such as their work culture and connectedness to the rural community. This heightened vulnerability may, in part, be explained by a phenomenon known as culture shock [28] or transition shock [29], caused by a misalignment between expectations and reality of entering the nursing workforce.

The vulnerability of early career nurses during the transition into the workplace can put them at risk of negative outcomes associated with poor workplace culture. Clarke et al. [30] previously estimated that 60% of nurses will leave

their first job due to the behaviours of their colleagues. Our research demonstrated that for Sam, the segregation from colleagues was the primary reason for leaving her employment. Sam spoke about experiences of feeling like an outsider and the way that this influenced her life within and outside of work. In contrast, other nurses had experienced feelings of being “part of an extended family.” These experiences of the early career nurses as insiders versus outsiders reflect similar findings of research conducted by Ho et al. [31]. They described how early career nurses experienced “support and belonging” or “feeling unsupported and alienated” [31]. Explored through the lens of job embeddedness, Ho et al. [31] found that early career nurses who felt like outsiders were less likely to be retained in the workplace. Considered in relation to a rural context, it is potentially even more important to connect early career nurses to their workplace and colleagues, especially those new to the area or without strong existing connections who are more likely to be socially and geographically isolated.

In the context of early career nurse experiences and retention, engaging in socialisation tactics may be valuable for rural health organisations as they attempt to support newcomer nurses transitioning into the rural health workforce [32]. These tactics include various mechanisms focused on transforming “an outsider to an effective insider” [32] and supporting an employee to adapt to the new environment, behaviours, and knowledge. Suggested mechanisms to achieve this in nursing include structured rotations, staff support, ongoing education, and mentorship programs [6, 33, 34]. Research by Saks et al. [35] has demonstrated the relationship between socialisation tactics and newcomer adjustment, finding tactics that represent institutionalised socialisation were negatively related to factors such as intentions to quit and positively related to factors such as job satisfaction, performance, and organisational commitment. In the rural environment, further consideration should also be given to interplay between collective and individual socialisation due to the size of the population. Results from this study suggest that connections with colleagues may be of greater significance in rural areas due to the limited interpersonal interactions that occur outside of work, particularly for a newcomer to the community. Outside of socialisation tactics, our research also showed that some of the early career nurses felt that prior experiences such as having previously done shift work, having lived locally, or having skills that were transferable to this new environment acted as protective factors during their transition phase. These factors could be further explored in future research.

The implications of feelings of connectedness in rural nursing practice have previously been discussed by Conger and Plager [36]. They found that connectedness was essential for the retention of rural nurses and “graduates who reported a sense of disconnectedness when working in a rural community were less likely to remain in that community” [36]. An additional consideration discussed by Conger and Plager [36] was the experience of connectedness for rural nurses entering a new community. For nurses entering rural communities as outsiders, there is added complexity in establishing connections as they are starting with minimal

ties. The imperative to establish connections is significant due to its influence on both recruitment and retention of rural nurses [36]. This reflects the experience of several of the early career nurses discussed in our research as the rural origin nurses described maintaining connections as a protective factor, and those moving in from outside the communities described the connection as a primary influence on retention.

In research focused on understanding flourishing among rural nurses, Crawford [37] also identifies connection as important and that “rural nurse participants felt a deep connection to their communities and their role within the community as a nurse.” In this context, Crawford [37] used Edgar and Pattinson’s [38] definition of flourishing, which they relate to wellbeing, but point out that it additionally captures vulnerability and suffering to “create a framework through which one can meaningfully and constructively go on with one’s life” (p. 161). Crawford found that “working with a purpose” helped rural nurses flourish [37]. In our research, the early career nurses discussed being able to work with people who were important to them and/or a part of their community, as well as being able to provide a continuity of care and see the outcomes of their work. This was very similar to the activities attributed by Crawford as contributing to a sense of purpose and flourishing in rural nursing, including working across diverse role and skills, and the meaning behind each encounter with a patient [37].

Connection therefore plays an important role in shaping the experiences of rural nurses. Although the results of our research demonstrated that this role was largely positive, other research studies focused on rural nurses has demonstrated that connection to communities can create difficulties for some nurses when personal and professional boundaries become blurred [39, 40]. The experience of early career nurses in navigating professional and personal boundaries is worthy of future exploration.

Rural nursing has been acknowledged as a distinctly unique form of practice for more than 20 years [28, 41, 42]. It is therefore unsurprising that the early career nurses in this study identified it as such. Interestingly, the early career nurses did not reflect on their clinical practice as a significantly influential factor in their career decisions. They instead pointed to factors such as their connections with people, place, and profession as being primarily related to their employment location. This is different to the findings of similar research conducted by Rose et al. [33] who also used a phenomenological approach to explore the experiences of early career nurses in rural areas. Rose et al. [33] found several factors that influenced nurses’ experiences, including professional factors such as scope of practice, need for ongoing education, specialty rotations, and lack of staff and resources. They did, however, also find several personal factors that influenced the early career nurse experience, including the sense of community, importance of collegial support, and maintaining a work/life balance [33]. These differences in findings may be attributed to a difference in years of experience of the nurses recruited for Rose et al. [33] research as compared to our research. As several (10 out of

13) nurses interviewed by Rose et al. [33] had been practicing for >1 year, it is possible the time they had to adjust to their career and location may have changed the emphasis they placed on different factors that influenced their career decisions. The nurses in our research had all been practicing for ≤1 year and therefore had less time to establish personal and professional connections, thus placing these at the fore in their experiences.

This study has highlighted that connectedness and inclusion in both the workplace and the community for nurses during the period of transition cannot be underestimated and can impact on retention in rural areas. These findings have implications for employers and communities supporting nurses and emphasises the importance of prioritising, planning, and implementing practical strategies to promote inclusion, connectedness, and a positive workplace culture. Strategic and specific ways in which to assist early career nurses to experience a sense of belonging and embeddedness in the workplace and transition to the unique experience of rural nursing present an opportunity for future research.

There are a number of limitations inherent to the design of this study. Participants were recruited via their workplace and thus although steps were taken to ensure they understood the research would not affect their employment, it is possible some nurses perceived an association between the research and their employment. Asking participants to self-select participation in the project may also have resulted in nurses who had either very positive or very negative experiences opting to participate, as they may be more likely to want to discuss their experiences. Finally, as this research was exploratory, it is not generalisable to the broader population but instead provides a platform for further research on this topic.

5. Conclusion

This study demonstrates the vulnerability felt by early career nurses as they transition into a new profession and how this can result in a heightened response to experiences during the initial 12 months of practice. The nurses in this study described the distinctness of rural nursing as a profession, and the benefits associated with this type of practice, such as using a variety of skills and providing care, cross a continuum. Primarily, the nurses’ career decisions were influenced by their experience of connection to person, place, and profession. These results can be used to further conceptualise the importance of connection and belonging in achieving retention of staff in rural areas.

Data Availability

Due to the ethical obligations of the authors, the data used in this study are not available.

Conflicts of Interest

The authors declare that they have no conflicts of interest.

Acknowledgments

The authors would like to acknowledge the work of Jayne Lawrence, Melissa Sinclair, and Annie Skipworth who contributed to the design of a larger mixed methods study from which the data used in this study were derived. The authors of this research are employees of Three Rivers Department of Rural Health, funded by the Australian Government under the Rural Health Multidisciplinary Training (RHMT) Program. Open access publishing was facilitated by Charles Sturt University, as part of the Wiley-Charles Sturt University agreement via the Council of Australian University Librarians.

Background. Haematology nurses in Singapore experience a highly stressful work environment and increased workload due to the growing number of patients and complex treatment regimens. High job demands can lead to burnout and high staff turnover rates, which compromises the quality of patient care. **Aims.** To assess perceived work demands, levels of social support from colleagues, professional quality of life (ProQOL), and turnover intentions among haematology nurses and examine whether demographic and occupational characteristics, perceived job demands, and support were associated with ProQOL and turnover intentions. **Design.** A descriptive, correlational, and cross-sectional design was used in this study. **Methods.** A convenience sample of 60 haematology nurses working at a tertiary hospital in Singapore completed a self-administered survey. Perceived job demands, support from colleagues, ProQOL, and turnover intentions were measured using the Copenhagen Psychosocial Questionnaire (COPSOQ III), Professional Quality of Life Scale version 5 (ProQOL5), and Turnover Intention Scale (TIS-6). Descriptive statistics, chi-square test, and multiple linear regressions were employed for data analysis. **Results.** Haematology nurses face high cognitive and emotional demands and receive high levels of support from colleagues at work. The majority of the participants reported moderate to high levels of compassion satisfaction (78.3%), burnout (76.7%), and secondary traumatic stress (81.7%). 53.3% of the participants expressed their intention to leave. Perceived job demands were significant predictors of haematology nurses' ProQOL and turnover intentions. Compassion fatigue also significantly predicts turnover intentions. **Conclusion.** The high levels of burnout and secondary traumatic stress reported by haematology nurses highlight an urgent need to implement strategies to help nurses cope with the high work demands and reduce their levels of compassion fatigue. **Implications for Nursing Management.** The findings in this study can help nursing leaders understand haematology nurses' perceived job demands and ProQOL, to develop strategies to improve the workplace environment and retention.

1. Introduction

The global nursing workforce shortage is a growing issue that has been exacerbated by the COVID-19 pandemic [1]. Nursing workforce shortages are especially significant in the oncology and haematology disciplines [2]. Besides monitoring patients closely for adverse treatment side effects and toxicities, oncology and haematology nurses are also being subjected to highly emotive situations on a regular basis and are at high risk of occupational exposure from chemotherapy administration [2]. The hazardous and highly

stressful work environments of cancer care present challenges for organisations to recruit and retain oncology and haematology nurses [2, 3]. In Singapore, the growing numbers of haematology patients coupled with new and complex treatment regimens, such as the chimeric antigen receptor (CAR) T-cell therapy, have increased workload and demands for nurses in the haematology discipline. Retention of experienced haematology nurses is essential to support these demands and maintain quality patient care and optimal patient outcomes [2]. Therefore, gaining an improved understanding of factors that influence work-related

outcomes such as professional quality of life and turnover intentions is crucial to retaining nurses in this discipline.

Haematology nurses have frequently been classified as a subset of oncology nursing in published research studies [4, 5]. However, providing clinical care for patients with haematological disorders comes with unique circumstances and challenges. Haematological malignancies have unpredictable disease trajectories, and treatment regimens are often more complex and intensive than those administered for solid tumours [4]. Therefore, haematology patients spend significantly more time in the hospital, especially those who undergo haematopoietic stem cell transplants [5]. The prolonged interaction allows haematology nurses to develop sustained and therapeutic relationships with the patients, which increases nurses' vulnerability to emotional distress and burnout when the patients experience poor outcomes or are potentially at the end of life [4]. Burnout and stress can lead to high staff turnover rates, further aggravating the haematology nursing workforce shortage [2].

Workload or workplace demands have been identified as a primary factor associated with job dissatisfaction, burnout, coping, and intention to leave the discipline among haematology and oncology nurses [6–9]. Studies had revealed that nurses felt guilt or frustration when workload or workplace demands prevented them from spending sufficient time talking to patients or developing a connection with them [10–13]. Nurses deem having ample time with patients to be crucial in the provision of high-quality care and being unable to do so could likely be a precipitating factor for compassion fatigue [10–13]. Workload was found to be the sole independent significant predictor of exhaustion and the single factor that differentiates nurses who were experiencing high levels of exhaustion from those experiencing low to average levels of exhaustion among 230 Australian cancer nurses [7].

Teamwork and support from colleagues were identified as a key resource that helped oncology and haematology nurses cope with challenges at work [10, 12, 14]. Nurses who experienced secondary traumatic stress expressed that social support from their colleagues helped them cope with difficult situations at work and that their colleagues understood them the best [12]. Likewise, early career nurses reported that their coworkers were the only ones who could relate to the workplace frustrations that they experienced, and support from coworkers helped them to buffer stress during work [10]. In addition, teamwork and support from colleagues were found to reduce compassion fatigue and burnout in oncology and haematology nurses [3, 13, 15]. Oncology nurses in the United States and Canada were revealed to be less likely to experience compassion fatigue and burnout and derive more compassion satisfaction when they perceived team cohesiveness at work [15].

Professional quality of life (ProQOL) refers to the quality of life perceived by people who work in a helping profession and comprises compassion satisfaction and compassion fatigue [16]. Compassion satisfaction refers to the positive feelings derived from work, whereas compassion fatigue encompasses burnout and secondary trauma from nursing patients suffering or experiencing traumatic stress [16].

Studies that examined demographic variables such as age, gender, marital status, education, and work-related variables such as years of experience associated with ProQOL reported inconsistent findings [15, 17–19]. Besides that, studies conducted in different countries have also reported varying scores and levels of compassion satisfaction, burnout, and secondary traumatic stress among oncology and haematology nurses.

The mean scores of compassion satisfaction ranged from 31.81 to 42.6 [15, 17–20]. For burnout, the mean scores reported ranged from 21.14 to 28.38 [15, 17–20]. The mean compassion fatigue scores reported by oncology nurses in Portugal and China were 25.82 and 21.39, respectively [17, 19]. Besides ProQOL scores, the levels of compassion satisfaction, burnout, and secondary traumatic stress or compassion fatigue among oncology and haematology nurses based on cutoff scores proposed in the ProQOL manual were reported in some studies. In Korea, approximately 75% to 80% of the participants reported average to high levels of burnout and secondary traumatic stress [18]. Duarte and Pinto-Gouveia [17] described similar findings among participants working in different public hospitals in Portugal. In comparison, 82% to 89% of the nurses in Spain expressed average to high levels of burnout and secondary traumatic stress [21]. Despite more participants reporting higher levels of burnout and secondary traumatic stress, a higher percentage (34.3%) of nurses in Spain reported high compassion satisfaction levels compared to the nurses in Korea (28.1%) [18, 21].

Turnover intentions were found to be associated with ProQOL, work demands, and demographic or occupational characteristics of haematology and oncology nurses. Low compassion satisfaction, high burnout, and high secondary traumatic stress were revealed to be significantly associated with participants' intentions to transfer to another unit [21]. Compassion satisfaction and burnout were also reported to be significant predictors of turnover intention among oncology nurses in the United States [20]. In contrast, Wells-English et al. [20] did not find that secondary traumatic stress significantly predicts turnover intentions. Similarly, turnover intentions were only found to be associated with compassion satisfaction and burnout, not secondary traumatic stress [18]. Besides that, Jang et al. [18] also showed that 51.6% of the 285 Korean oncology nurses surveyed had a turnover intention. Interviews conducted by Saifan et al. [22] revealed that some Jordanian nurses working with cancer patients faced difficulties balancing between work demands and their personal lives, which led to intentions to leave their jobs. In contrast, Giarelli et al. [11] found that 18 out of 20 nurses working in a haematology-oncology unit expressed intention to continue working in oncology nursing within the next five years. However, it is of note that none of the 20 participants reported low levels of compassion satisfaction or high levels of burnout and secondary traumatic stress [11]. 59.8% of the nurses surveyed in Turkey wanted to change their wards and clinical speciality, with workload being cited as one of the main reasons for that intent [8]. Meanwhile, Park and Ahn [23] investigated the correlations between demographic and occupational

characteristics and turnover intentions of Korean nurses and found age, job ranking, work experience, type of employment, and place of work were significantly associated with turnover intentions.

Findings from the literature review suggested that workplace demands and support from colleagues were potentially associated with oncology and haematology nurses' ProQOL, burnout, stress, and intention to leave. The Job Demands-Resources (JD-R) model postulates that every occupation involves job demands and resources, which are risk factors linked to job-related stress [24]. Examples of job demands include high patient load or emotionally taxing interactions with patients and family [24]. On the other hand, job resources can be found at the organisational, interpersonal, or task levels and include job security, autonomy, and supervisor or coworker support [24]. The JD-R model proposes that job demands and resources set in motion two separate psychological processes in developing work-related strain and motivation [25]. The first is a health impairment process, whereby jobs with high or chronic job demands such as haematology nursing drain employees' physical and mental resources and result in adverse outcomes, such as compassion fatigue and turnover intentions [24]. The second is a motivational process, in which job resources are assumed to promote work engagement and bring about positive outcomes, including organisational commitment and intention to stay [24].

Inconsistent findings were reported on the associations between demographic and occupational characteristics, job demands, support from colleagues, ProQOL, and turnover intentions of oncology and haematology nurses. Besides that, there is a paucity of research that examines perceived job demands and resources and how these factors influence nurses' ProQOL and turnover intentions, specifically among haematology nurses, as all the studies reviewed considered haematology and oncology nurses as a homogenous group. Therefore, this study aimed to assess the perceived work demands, levels of social support from colleagues, ProQOL, and turnover intentions among haematology nurses in Singapore and examine whether demographic and occupational characteristics, perceived job demands, and support from colleagues were associated with haematology nurses' professional quality of life and turnover intentions. The constructs and variables measured in this study are summarised in Figure 1 using the JD-R model.

2. Methods

2.1. Research Design and Sample. This study employed a descriptive, correlational design to measure the perceived job demands, support from colleagues, ProQOL, and turnover intentions in haematology nurses and explore the relationships among the variables. Data were collected using a cross-sectional online survey. A convenience sample of registered and enrolled nurses with at least six months of haematology experience working at two inpatient haematology wards at a large tertiary hospital in Singapore was recruited for the study. Advanced practice nurses, resident

nurses, and nurses in management roles, including nurse managers and nurse clinicians, were excluded from the study due to differing job scopes and work demands. Nurses on leave during the data collection period were also excluded. 112 nurses met the inclusion criteria. Participants were recruited through two avenues. A recruitment e-mail containing information about the study and a QR code and link to the survey was sent to all eligible nurses who met the inclusion criteria. A follow-up e-mail reminder was sent one week after the initial invitation. In addition, face-to-face information sessions were conducted during daily ward staff meetings for clarifications regarding the study and to enhance participation.

2.2. Data Collection. Data were collected over two weeks in October 2021 via Form.gov.sg, a secure self-service online form builder. Participants could review information about the study on the survey web page before answering the questions. Consent was implied when participants submitted a completed survey. Participants were reassured that they could take a break or choose not to complete or submit the survey at any time during the survey process if the questions made them uncomfortable. The survey included demographic and occupational data questions and three instruments to measure workplace demands, support from colleagues, ProQOL, and turnover intentions. Each section was prefaced with introductory information on the variables measured and instructions on selecting the response options. Upon submission of the survey, all responses were stored in an encrypted format on the Form.gov.sg server, and only research team members could view the data.

2.3. Outcome Measures and Instruments. In this study, job demands were conceptualised as quantitative, cognitive, and emotional demands. Quantitative demands refer to the number of tasks nurses have to achieve during their work and whether they have sufficient time to complete these tasks in a satisfactory manner [26]. Cognitive demands are tasks or duties requiring the nurses' mental effort [26, 27]. Besides that, haematology nurses experience emotional demands when they manage the emotions of patients and their loved ones at work [26]. Job resources were examined through nurses' perceptions of whether they could obtain support from their colleagues when necessary [26]. ProQOL was chosen as the work-related outcome to investigate haematology nurses' well-being and the development of work-related strain and motivation in this study. Haematology nurses care for patients who go through suffering and highly stressful events and are likely to experience both positive and negative feelings associated with the care they provide. ProQOL provides a balanced perspective of the positive and negative aspects of haematology nursing, including compassion satisfaction and compassion fatigue. This study also examined turnover intentions to determine whether haematology nurses' perceived levels of job demand, support from colleagues, and ProQOL are predictors of their intention to leave.

FIGURE 1: Summary of the constructs and variables measured using the JD-R model.

This study combined three independently validated instruments and specific demographic and occupational data questions to measure the variables of interest. The instruments used included the third version of the Copenhagen Psychosocial Questionnaire (COPSOQ III), the Professional Quality of Life Scale version 5 (ProQOL5), and the 6-item Turnover Intention Scale (TIS-6).

2.3.1. Copenhagen Psychosocial Questionnaire (COPSOQ III). A short version of the COPSOQ III, comprising 45 items, was used to collect data on perceived job demands and social support received at work. The COPSOQ III is a public instrument. Therefore, the use of the questionnaire did not require consent on the condition that guidelines set out by the COPSOQ International Network were adhered to [28]. The COPSOQ III has been tested for validity and reliability in many countries worldwide and is widely used to assess psychosocial conditions in the healthcare industry [28]. Cronbach's alpha for the psychosocial dimensions under demands at work ranged from 0.77 to 0.80 [26]. For the dimension of social support from colleagues, Cronbach's alpha was reported to be 0.87 [26]. The short version used for this study was adapted based on the COPSOQ International Network guidelines [28]. The survey included mandatory items labelled CORE in the COPSOQ III and was supplemented by items labelled MIDDLE or LONG from the dimensions of interest [28]. Participants were asked to select the most appropriate response for each question on a 5-point Likert scale. Each question was scaled to the intervals 0 to 100, with each response having equal weight [28]. The mean

score for each dimension was calculated by adding up the scores of each item under that dimension and obtaining the average [26, 28]. A mean composite score was computed for overall job demands based on the average scores of the three dimensions. Higher scores indicate greater job demands and more social support received on a range of 0 to 100.

2.3.2. Professional Quality of Life Scale (ProQOL5). The ProQOL5 is commonly used to measure the positive and negative effects experienced by people working in a helping profession, such as nurses, and has three subscales: compassion satisfaction, burnout, and secondary traumatic stress [16]. The burnout and secondary traumatic stress subscales were combined to measure compassion fatigue [16]. The instrument's validity and reliability have been established through extensive research, with Cronbach's alpha for the three subscales ranging between 0.72 and 0.87 [16]. The ProQOL Office at the Center for Victims of Torture provided permission to use the scale for this study.

The ProQOL5 is a 30-item instrument that uses a 5-point Likert scale with responses ranging from *never* to *very often* (1 = never, 5 = very often) [16]. Participants were asked to select the response that best reflected the frequency of each experience in the last 30 days. For this survey, the words in the italicised brackets were changed to *nurse* or *nursing* to help participants read the scale smoothly, as suggested in the ProQOL manual [29]. Each subscale is comprised of ten questions. Compassion satisfaction was measured using questions 3, 6, 12, 16, 18, 20, 22, 24, 27, and 30 [16]. Questions 1, 4, 8, 10, 15, 17, 19, 21, 26, and 29 were used to

measure the burnout component [16]. Secondary traumatic stress was measured by the remaining questions [16]. The scores for each subscale were added up, and the mean scores for burnout and secondary traumatic stress were combined to obtain the mean score for compassion fatigue. Cutoff scores for each subscale were also calculated based on a quartile system proposed in the ProQOL manual to identify participants with low, moderate, or high levels of compassion satisfaction, burnout, and secondary traumatic stress [16]. Finally, the scores for each subscale were converted to *t* scores for comparison and further analysis [16].

2.3.3. Turnover Intention Scale (TIS-6). The 6-item Turnover Intention Scale (TIS-6), adapted from a 15-item scale developed by Roodt [30], was used to measure haematology nurses' intention to leave the organisation [31]. The TIS-6 was developed based on the Theory of Planned Behavior and was determined to be a reliable and valid scale used to measure turnover intentions or predict actual turnover, with a Cronbach's alpha of 0.80 [31]. In addition, exploratory factor analysis was conducted to establish the factorial validity of the scale, with item loadings ranging between 0.73 and 0.81 [31]. Responses to the TIS-6 were measured on a 5-point Likert scale [31]. A total score was obtained by adding all item scores, and the midpoint of the scale, which is 18, was used as a cutoff to indicate turnover intention. The author provided permission to use the TIS-6 for this study.

2.4. Ethical Considerations. Ethics approval was obtained from the SingHealth Centralised Institutional Review Board (Reference number: 2021/2564). Participation in this study was entirely voluntary. Eligible nurses were provided with information about the study, study participation, contact information of the investigators, survey sections, and estimated time required to complete the survey in the recruitment e-mail and survey web page. Research team members answered all questions regarding the study and survey. Participants were informed that consent was implied when they submitted a completed survey, but they could not withdraw from the study after their responses were recorded due to the anonymity of the survey. The survey was anonymous to ensure privacy and confidentiality. No personal data that made the participants identifiable were collected. Once submitted, all survey responses were encrypted end-to-end and stored in an encrypted format on the Form.gov.sg server. Data collected were kept confidential. A private key was generated during the survey form creation to ensure that only research team members had access to the responses. Research data were stored according to institution policy.

2.5. Data Analysis. All survey responses were exported to Microsoft Excel, where the data were labelled, coded, and checked for missing values. Reverse scoring for specific items in the COPSOQ III and ProQOL5 was performed in Microsoft Excel. The response data were then imported to SPSS v27.0 for analysis. Descriptive statistics were employed to describe and analyse the demographic and occupational

characteristics of the participants, perceived job demands, support from colleagues, subscales of ProQOL, and turnover intentions. Statistical tests used included frequency distribution, mean, range, and standard deviation. The chi-square test was utilised to assess for significant associations between turnover intentions and the demographic and occupational characteristics of the participants. Some demographic and occupational characteristics data were regrouped before the test was performed. Next, standard multiple regression was carried out in three parts. The first regression analysis was performed to identify factors that significantly predict perceived job demands and support from colleagues. The subsequent analysis examined the factors predicting ProQOL in the participants. Finally, the last standard multiple regression was used to determine whether perceived job demands, colleague support, and ProQOL were significant predictors of turnover intentions. The assumptions of multiple regression analysis, including multivariate outliers, multicollinearity, normality, linearity, and homoscedasticity of residuals, were assessed and met in all models. A significance level (*p* value) of less than 0.05 was used to determine statistical significance.

3. Results

3.1. Characteristics of Participants. A total of 60 respondents completed the surveys with a response rate of 54%. Based on the sample size of 60 in this study, power analysis was performed. The power of the test to detect a large effect (Cohen's $f^2 = 0.35$) was 0.858, a medium effect (Cohen's $f^2 = 0.15$) was 0.454, and a small effect (Cohen's $f^2 = 0.02$) was 0.088. Each respondent answered all the survey questions; therefore, all 60 responses were included in the data analysis. Participants' demographic and occupational characteristics are summarised in Table 1. There were 28 participants aged between 21 and 30 (46.7%), and the remaining were between 31 and 60 years of age ($n = 32$, 53.3%). The majority of the participants were female ($n = 51$, 85%). There was an even distribution between participants who were single ($n = 32$, 53.3%) and married ($n = 28$, 46.7%). More than half of the participants do not have children ($n = 35$, 58.3%). With respect to the highest education qualification, 48.3% of the participants held a bachelor's degree ($n = 29$), 25% had a diploma ($n = 15$), and 11.7% had an advanced diploma ($n = 7$). Senior staff nurses and staff nurses represented 40% ($n = 24$) and 36.7% ($n = 22$) of the study sample, respectively. Assistant Nurse Clinicians made up the smallest number of responses ($n = 3$, 5%). Most of the participants ($n = 53$, 88.3%) reported being on rotating shifts. The haematology experience of the participants ranged from 1 to 33 years, with a mean of 9 years and a standard deviation (SD) of 7.65 years. The reported nursing experience of participants ranged from 1 to 40 years, with a mean of 11.99 years and an SD of 9.94 years.

3.2. Perceived Job Demands and Social Support from Colleagues. The participants reported a mean job demands score of 56.61 (SD = 12.81). The quantitative, cognitive, and

Nursing	11.99 (9.94)	1.0–40.0

emotional demands scores were 41.46 (SD = 15.27), 69.90 (SD = 14.67), and 58.47 (SD = 20.21), respectively. The mean score for social support from colleagues was 65.42, with a standard deviation of 19.71. Participants reported a maximum score of 100 for cognitive demands, emotional demands, and social support from colleagues. In terms of cognitive demands, 53.3% ($n=32$) and 58.3% ($n=35$) of the participants selected “Always” as a response to the questions “Do you have to keep your eyes on lots of things while you work?” and “Does your work require that you remember a lot of things?”, respectively. For emotional demands, 58.3% ($n=35$) of the respondents indicated that their work was emotionally demanding to a large or very large extent. On the other hand, 21.7% ($n=13$) of the participants answered “Always” when asked, “How often do you get help and support from your colleagues, if needed?”

3.3. Professional Quality of Life. Table 2 presents the ProQOL raw scores and levels reported by the participants. The mean raw compassion satisfaction, burnout, and secondary traumatic stress scores were 36.20 (SD = 7.07), 25.93 (SD = 5.54), and 25.32 (SD = 6.37), respectively. The mean raw compassion fatigue score was 25.63 (SD = 5.40). The cutoff scores for each subscale were calculated based on a quartile system proposed in the ProQOL manual. Majority of the participants reported moderate to high levels of compassion satisfaction ($n=47$, 78.3%). On the other hand, most of the participants reported moderate to high levels of burnout ($n=46$, 76.7%) and secondary traumatic stress ($n=49$, 81.7%).

3.4. Turnover Intentions. The mean turnover intention score was 18.32 (SD = 5.00). A cutoff score of 18, based on the midpoint of the TIS-6 scale, was used to determine turnover intentions. A score of 18 or more indicated that the participant had an intention to leave the organisation. More than half of the participants reported an intention to leave the organisation ($n=32$, 53.3%).

3.5. Relationships between Demographic and Occupational Characteristics, Perceived Job Demands, Social Support from Colleagues, Professional Quality of Life, and Turnover Intentions. Initial standard multiple regression models revealed that there is no association between demographic and occupational characteristics and participants' perceived job demands and job resources (all $p > 0.05$). Next, both perceived job demands and job resources were entered as independent variables, together with the demographic and occupational characteristics, in the standard multiple regression analysis to determine their predictive relationships on the ProQOL of participants. Two models were constructed, one each for compassion satisfaction and compassion fatigue. Table 3 presents the results of the two standard multiple regression models. In the compassion satisfaction model, highest education qualification ($B=8.59$, $p=0.001$) and job demands ($B=-0.31$, $p=0.002$) were identified to be significant predictors of compassion satisfaction. Education level was a positive predictor of compassion satisfaction, while job demands were negatively associated with compassion satisfaction. The two variables accounted for a significant 48% of the variability in the participants' compassion satisfaction ($R^2=0.48$, $p \leq 0.001$). In the compassion fatigue model, only job demands were significantly associated with compassion fatigue ($B=0.249$, $p=0.015$). Job demands significantly accounted for 32% of the variance in compassion fatigue reported by the participants ($R^2=0.32$, $p=0.009$).

Finally, the relationships between the participants' demographic and occupational characteristics, perceived job demands, job resources, ProQOL, and turnover intentions were investigated using the chi-square test and standard multiple regression analysis. The chi-square test showed no significant association between the sample characteristics and turnover intentions (all $p > 0.05$). Therefore, only years of haematology experience was entered into a standard

TABLE 2: Professional quality of life ($N = 60$).

Subscales	<i>n</i> (%)	Mean	SD	Min	Max
<i>Compassion satisfaction</i>		36.20	7.07	20	50
High	14 (23.3)				
Moderate	33 (55.0)

<i>Secondary traumatic stress</i>		25.32	6.37	14	44
High	12 (20.0)				
Moderate	37 (61.7)				
Low	11 (18.3)				
<i>Compassion fatigue*</i>		25.63	5.40	15	42

*Combined mean score of burnout and secondary traumatic stress. Cutoff scores proposed in the ProQOL manual based on a quartile system. Compassion satisfaction: low = 30 or less; moderate = between 31 and 42; high = 43 or more. Burnout: low = 21 or less; moderate = between 22 and 30; high = 31 and more. Secondary traumatic stress: low = 19 or less; moderate = between 20 and 30; high = 31 or more.

multiple regression analysis with perceived job demands, job resources, compassion satisfaction, and compassion fatigue to estimate the proportion of variance in turnover intentions that can be accounted for by these variables. Table 4 presents the results of the standard multiple regression analysis. In the constructed model, only job demands ($B = 0.168$, $p \leq 0.001$) and compassion fatigue ($B = 0.187$, $p = 0.016$) were identified to be significant predictors of turnover intentions. Both job demands and compassion fatigue were positively associated with turnover intentions. The two variables accounted for a significant 54% of the variability in turnover intentions of the participants ($R^2 = 0.54$, $p \leq 0.001$).

4. Discussion

Overall, the participants in this study reported a moderate level of workplace demands ($M = 56.61$, $SD = 12.81$). The results revealed that the nurses reported a higher level of cognitive ($M = 69.90$, $SD = 14.67$) and emotional ($M = 58.47$, $SD = 20.21$) job demands compared to quantitative ($M = 41.46$, $SD = 15.27$) demands. This finding is consistent with previous studies [6, 9]. More than half of the participants in this study reported that they always must keep an eye on and remember lots of things while working. This reflects the nature of haematology nursing, as the nurses are accountable for administering complex treatment regimens and monitoring patients for treatment side effects and chemotherapy toxicities [4, 6]. Besides that, 58.3% of the participants expressed that their work was emotionally demanding to a large or very large extent. The personal attachment that haematology nurses develop towards the patients and families due to repetitive treatment cycles and witnessing the suffering and death of the patients under their care could be the reasons for the high perceived emotional demands [6, 9]. Therefore, providing haematology nurses with specialised training and frequent updates on the management of patients undergoing complex haematology

treatments and support on emotion management may help relieve the cognitive and emotional work demands on haematology nurses [7].

This study indicated that participants received a high level of social support from their colleagues ($M = 65.42$, $SD = 19.71$). This finding is notable as previous studies have suggested that support from colleagues helped oncology and haematology nurses to cope with difficult situations and stress at work [10, 12, 14]. Besides that, support from colleagues is a critical job resource that could enable haematology nurses to complete their tasks on time, which could explain the lower quantitative job demands reported by the participants in this study [24]. Hence, it is crucial to continue promoting teamwork and peer support among haematology nurses to protect them from the harmful effects of job-related stress and improve work engagement [24].

The compassion satisfaction ($M = 36.20$, $SD = 7.07$), burnout ($M = 25.93$, $SD = 5.54$), and secondary traumatic stress ($M = 25.32$, $SD = 6.37$) scores reported by the participants in this study were within the range reported in the existing literature that examined ProQOL in oncology and haematology nurses [15, 17–20]. However, the mean compassion satisfaction score reported by participants in this study was lower than those reported in Western countries, including the United States, Canada, and Portugal [15, 17, 20]. This finding suggests that haematology nurses in Singapore derive less professional satisfaction from their work than oncology and haematology nurses working in Western countries, which is likely due to the differences in the work environment and cultures between different countries [16]. In contrast, the mean burnout and secondary traumatic stress scores identified in this study are higher than those of most previous studies [15, 17, 19, 20]. Therefore, haematology nurses may experience more exhaustion and stress and are exposed to more traumatic stressful events at work compared to a homogenous population of oncology and haematology nurses [16].

Based on the cutoff scores proposed in the ProQOL manual, most of the participants in this study reported moderate to high levels of compassion satisfaction. However, most of the participants also reported moderate to high levels of burnout and secondary traumatic stress. This finding is congruent with the study conducted by Arimon-Pagès et al. [21]. This suggests that despite being rewarding and meaningful, the positive aspects of haematology nursing do not necessarily negate the burnout and stress experienced by haematology nurses [21]. Therefore, retention strategies should be aimed at both improving the professional well-being of haematology nurses and providing them with job-related and personal skills to perform their work effectively and cope with stressful events at work [10, 17, 21].

Giarelli et al. [11] found that only 2 out of 20 haematology nurses had intentions to leave oncology nursing. However, the results of this study revealed that 53.3% of the 60 haematology nurses surveyed had an intention to leave the organisation. This finding was similar to the results of previous studies conducted [18, 20, 21]. This high percentage of nurses expressing an intention to leave highlights a concern as turnover intentions are positively related to

actual turnover [31]. High staff turnover can, in turn, bring about significant consequences for the organisation, such as workforce shortage and poor quality of care and costs for rehiring and training of nurses [31]. Therefore, nursing leaders must understand and improve factors that influence haematology nurses' turnover intentions to retain them in the organisation and profession.

In terms of factors that predict perceived job demands and support from colleagues, no association was found between the demographic and occupational characteristics of participants and their perceived job demands and job resources. This finding suggests that haematology nurses' perceived job demands and resources are primarily influenced by the work environment and aspects of their job instead of individual characteristics.

Among the demographic and occupational characteristics of the participants, the highest education qualification was found to be the only significant predictor of compassion satisfaction. This finding is supported by previous research conducted [15, 18]. Haematology nurses with higher education qualifications may be better equipped with knowledge of the haematology disease processes and patient management, which allows them to provide better quality care to

patients and derive more satisfaction from their work [15]. Hence, organisations should encourage and support nurses in pursuing further education and training to improve their ProQOL.

This study also revealed that age, marital status, and years of experience in nursing and haematology did not predict compassion satisfaction or compassion fatigue. This is different from findings in previous studies in which age [15, 17, 18], marital status [18], and years of nursing and oncology experience [15, 18, 19] were found to be significantly associated with the ProQOL of participants. This could be related to the cultural differences between haematology nurses in Singapore and those overseas. One interesting finding to note is that years of haematology and nursing experience were not predictors of ProQOL. This may indicate that contrary to popular beliefs, experienced haematology nurses neither derive more satisfaction from their work nor are at higher risk for compassion fatigue due to their years of experience than early career haematology nurses. Experienced haematology nurses may have been exposed to more negative effects and stressful events from work compared to early career nurses [15, 17]. However, in their years of experience, they may also have gathered more

knowledge and expertise to cope with these difficult situations, which moderates the effect on compassion fatigue [15, 17].

Existing qualitative studies indicated that workplace demands could be a precipitating factor for compassion fatigue as nurses are prevented from having ample time to interact with patients and provide quality care [10–13]. The findings from this study confirm past literature and the health impairment process in the JD-R model, in which job demands were found to be significant predictors of compassion fatigue. Furthermore, this study revealed that job demands were negatively associated with compassion satisfaction. As suggested by previous studies, high job demands could prevent haematology nurses from spending sufficient time with patients and providing quality patient care, as nurses need to complete their tasks satisfactorily and keep their eyes on many things concurrently [10–13]. Besides increasing compassion fatigue, this can also cause haematology nurses to experience incongruence between their expectations and the actual patient care provided, leading to lower compassion satisfaction [15]. Therefore, organisations need to provide adequate support for haematology nurses to cope with the demands at work to increase their professional satisfaction and reduce their experience of compassion fatigue.

Perry et al. [13] revealed that colleague support helped reduce the experience of compassion fatigue in oncology nurses. Similarly, Wu et al. [15] reported that perceptions of team cohesiveness reduced oncology nurses' likelihood of experiencing compassion fatigue and increased the compassion satisfaction derived by the nurses. In contrast, this study found that social support from colleagues was not significantly associated with both compassion satisfaction and compassion fatigue in haematology nurses in Singapore. This finding challenges the second proposition of the JD-R model, which suggests that job resources promote work engagement in employees [25]. Therefore, further studies are warranted to investigate the effects of other job resources, including autonomy, supervisor support, and meaning of work, on haematology nurses' ProQOL.

Finally, this study found that job demands and compassion fatigue were significant predictors of turnover intentions for haematology nurses in Singapore. This finding is well supported by previous literature and the JD-R model [8, 12, 13, 18, 20–22, 25]. Existing studies indicate that job demands have significant effects on oncology and haematology nurses' coping, exhaustion, and satisfaction at work, which could influence their decision to leave the organisation or profession [6–9]. Besides that, haematology nurses might face challenges juggling between demands at work and their personal lives, leading to intentions to leave [22]. Similarly, compassion fatigue can have adverse effects on haematology nurses, including physical and psychological exhaustion, difficulty in establishing and maintaining personal relationships, and negative attitudes towards work [12, 13]. These effects could potentially influence haematology nurses' intention to leave the organisation, discipline, or profession [12, 13]. Hence, in addition to helping haematology nurses cope with job demands, interventions must

be taken to reduce burnout and secondary traumatic stress experienced by this group of nurses to retain them in the discipline and organisation.

This study is one of the few that addressed haematology nurses as a heterogeneous sample instead of classifying them as a subset of oncology nurses. The study also contributed to understanding how each variable interacts to influence work-related strain, professional satisfaction, and turnover intentions in haematology nurses. Despite that, this study had some design-related limitations that should be noted. Inferences about causal relationships could not be made in this study as a cross-sectional design was used. A second limitation of this study was the sampling bias related to using a convenience sample. The nurses who chose to participate in the study might not represent the population, limiting the generalisability of the study's findings. Using self-administered surveys for data collection can eliminate interviewer bias and allow participants to remain anonymous. However, self-reports are more susceptible to response biases, which might distort the findings. Finally, the small sample size limits the power to detect medium and small effect and generalisability of the study findings. Therefore, it is recommended that the study is replicated with a large random sample from multiple centres or countries to improve the generalisability of the findings. Researchers can also conduct a longitudinal study to examine the long-term effects of job demands on haematology nurses' ProQOL and turnover intentions. Besides that, future research can consider exploring other predictors that influence the above psychosocial factors and outcomes, including personality and resilience of participants, autonomy, and supervisor support.

5. Implications for Nursing Management

Nursing leaders and nurse managers can engage nurses in conversations to understand their needs and how the organisation can support them in managing demands at work [11]. Strategies can be developed at organisation level to improve the workplace environment to help nurses cope with work demands and enhance their professional quality of life. For example, organisations can provide education and training for haematology nurses to equip them with the specialised knowledge, skills, and competencies to cope with the demands at work. Training programs can focus on haematology disease processes and patient management, emotion management skills, and building resilience to improve the well-being of haematology nurses and prevent compassion fatigue [21, 32]. Besides that, organisations can adopt technology and informatics, such as wearable devices and smart pumps, to reduce workplace demands placed on haematology nurses. Nursing leaders can also establish formal support mechanisms such as counselling and debriefing sessions for nurses to express their emotions and grief after the loss of a patient to prevent or reduce compassion fatigue in haematology nurses [21, 22]. More emphasis can be placed on mental health of haematology nurses and promoting self-care to cope with the emotional demands at work and reduce the effects of compassion fatigue [11, 12].

6. Conclusion

This study revealed that haematology nurses in Singapore face high cognitive and emotional demands at work. Although most of the nurses reported moderate to high compassion satisfaction, the majority of them also experienced moderate to high levels of burnout and secondary traumatic stress. Job demands significantly predict the ProQOL of haematology nurses. Besides that, both job demands and compassion fatigue were significant predictors of turnover intentions in haematology nurses. The high percentage of haematology nurses reporting an intention to leave the organisation in this study highlights an urgent need to implement strategies to help nurses cope with the high work demands and reduce their levels of compassion fatigue, to improve staff retention.

Aims. This study aimed to analyze the effects of the surgery preparation time on patient outcomes. **Background.** Postoperative complications have a decisive effect on postoperative survival. The anesthesia time is a crucial determinant of such complications. Competent operating room nurses can shorten the surgery preparation time, which is the time from when anesthesia is first administered to the making of the surgical incision. The shortening of this preparation time can shorten the anesthesia time and may reduce postoperative complications. However, discussion of this preparation time is insufficient. Therefore, this study analyzed the effect of the surgery preparation time on patient outcomes. **Methods.** From electronic health records data, this retrospective cohort study used the data of 1,944 patients who had been immediately admitted to the ICU after their surgery between 2017 and 2020. The patients were divided into two groups: ≥ 30 minutes preparation time and < 30 minutes preparation time groups. We performed chi-squared tests and *t*-tests to determine differences in preoperation, intraoperation, and post-operation characteristics of the patients and patient outcomes based on the surgery preparation time. Furthermore, we performed a multiple logistic regression by including 12 adjusted variables to determine the influence of the surgery preparation time on patient outcomes. **Results.** Among the 1,944 patients, 820 were in the ≥ 30 minutes preparation time group and 1,124 in the < 30 minutes preparation time group. The multiple logistic regression analysis showed that the surgery preparation time affects alertness (OR = 1.44; 95% CI: [1.09, 1.90]), ventilator application (OR = 1.32; 95% CI: [1.03, 1.70]), and length of stay in the ICU (OR = 1.69; 95% CI [1.16, 2.47]). **Conclusions.** The surgery preparation time affects postoperative patient outcomes. The competence of operating room nurses is the most essential aspect of the surgery preparation time. **Implications for Nursing Management.** It is important to analyze operating room nurses' tasks, standardize the tasks, and educate nurses according to their experience level to reduce the surgery preparation time and improve patient outcomes.

1. Background

The number of surgeries is increasing steeply every year worldwide [1]. While the risk of intraoperative complications is decreasing with the development of medical technologies, the risk of postoperative complications is increasing. Every year, tens of thousands of patients experience postoperative complications [2]. Notably, the risk of postoperative complications is higher in major surgeries than in minor ones, with an incidence rate of up to 25% [3].

Postoperative complications have been found to have a decisive effect on postoperative survival [4]. Reportedly, two million patients die every year due to postoperative complications [5]. In addition, the mortality rate within 60 days of surgery is 3.4 times higher if complications occur

[6]. Common postoperative complications include pain, delirium, pressure ulcers, decreased bowel movement, infection, and bleeding. These complications result in patient outcomes such as admission to the intensive care units (ICUs), prolonged hospitalization, and increased healthcare costs [7–9].

The factors affecting postoperative patient outcomes can be delineated as internal and external. Internal factors are factors related to the patient, such as demographic characteristics, lifestyle, diseases, surgical history, degree of activity, and intraoperative status [10, 11]. External factors are related to the surgical processes, such as the time and method of anesthesia, anesthetic agent, surgery time, surgery site and method, surgery position, and intraoperative specifics [11–13].

Among these factors, the factors that are controllable and can reduce postoperative complications and improve patient outcomes are largely external. Notably, among all external factors, anesthesia time has the most significant influence. Prolonged anesthesia time is associated with the risk of nausea, vomiting, infection, and bleeding as well as venous thromboembolism in serious cases [14]. It contributes to increased length of stay and healthcare costs, as do postoperative complications [15–17].

The anesthesia time can be divided into three periods: the surgery preparation, surgery, and dressing periods. The “surgery preparation period” begins with the initiation of anesthesia and continues until the surgical incision is made [18–21]. During this period, the patient is prepared for surgical positioning [19, 22, 23], while operating room (OR) nurses endeavor to maintain a sterile environment by handling surgical equipment, ensuring cleanliness, and performing sterilization. They also assist the patient in donning the surgical attire and maintaining its sterility. These efforts are aimed at preventing surgical site infections [23–26]. The “surgery time” starts when the surgical incision is made and ends when sutures are made [22, 27, 28]. This is the duration of the surgical procedure and is recorded as the total time on the surgical record sheet. Reducing this duration can positively affect patient outcomes [8, 29, 30]. Finally the “dressing period” spans from the completion of the operation to the time the anesthesia completely ends. During this period, the patient’s condition is checked and necessary disinfection and cleanup actions are performed. This period includes the time taken for the patient to prepare for movement in the operating room.

The surgery preparation time is when the work of OR nurses is the most concentrated. Nursing work performed during the surgery preparation time can be divided into the tasks performed by scrub and circulatory nurses in sterile and nonsterile fields, respectively. Scrub nurses are tasked with various responsibilities aimed at facilitating the surgical procedure. These responsibilities encompass delineating the parameters of the sterile field, arranging sterilized surgical instruments, and aiding the surgical team in donning gloves and gowns [31, 32].

Meanwhile, circulatory nurses primarily handle tasks outside the sterile field in the OR. This includes protecting the integrity of the sterile field, assisting the scrub nurse in the gowning of the surgical team, delivering the items needed for surgery into the sterile field, and arranging the positioning of surgical equipment [25, 26]. Thus, the surgery preparation period is a critical juncture in which OR nurses’ expertise and proficiency exert a significant influence on patient safety and surgical efficiency.

Competent OR nurses can shorten the surgery preparation period, which can shorten the anesthesia time, thereby contributing to reducing the instances of postoperative complications. Most studies have analyzed OR nursing tasks and quantitatively measured the time required to prepare for surgery. Consequently, research remains scant on the association between the surgery preparation time and patient outcomes [18, 19, 21]. Thus, this study aimed to analyze the impact of surgery preparation time on

postoperative patient outcomes, such as the presence or absence of medical interventions.

2. Methods

2.1. Study Design. This was a retrospective cohort study conducted using electronic health record (EHR) data.

2.2. Data Source. This study used an EHR dataset that was created for the primary study to predict pressure injuries in ICUs. This EHR dataset was extracted from the EHR system of the University Hospital in Seoul, South Korea. It contained the clinical data of 6,555 patients who were hospitalized and discharged from medical and surgical ICUs between January 1, 2017, and February 28, 2020. The dataset contained data on 1,106 variables extracted from various sources, such as anesthesia, surgery, and recovery records, nursing information records, clinical observation records, laboratory clinical pathology tests, medication administration records, blood transfusion records, instrument and device insertion and removal records, and nursing diagnoses.

2.3. Study Population. Of the 6,555 individuals enrolled in the primary study, we used the data of 1,944 individuals admitted to the ICU immediately after their surgery (Figure 1). The data of patients who were aged 19 or older and stayed in the ICU for three days or more were included in our analysis. We excluded the data of patients who were admitted to the general ward after surgery and were later transferred to the ICU due to increasing severity.

2.4. Study Variables. From the data source, we used the data on surgery preparation time (the main independent variable), eight patient outcome variables, patient demographic variables, and adjusted variables in our analysis.

2.4.1. Surgery Preparation Time. Owing to a lack of a standard surgery preparation time, criteria for surgery preparation time vary across studies. In this study, the surgery preparation time was considered to be the period between the initiation of anesthesia to the making of the surgical incision. According to previous research, the average surgery preparation time ranges from 10 minutes to 57 minutes [18–21]. In this study, which targeted 1,944 participants, the average surgical preparation time was 30 minutes. Consequently, the study population was classified based on whether their surgery preparation time was 30 minutes or longer (≥ 30 minutes preparation time group) or less than 30 minutes (< 30 minutes preparation time group).

2.4.2. Patient Outcomes. To analyze the impact of the surgery preparation time on patient outcomes, we selected the postoperative patient outcomes, primarily nursing-sensitive ones, that could be observed in the ICU postoperatively. Consequently, eight outcomes were selected: alertness, number of nursing diagnoses related to postoperative

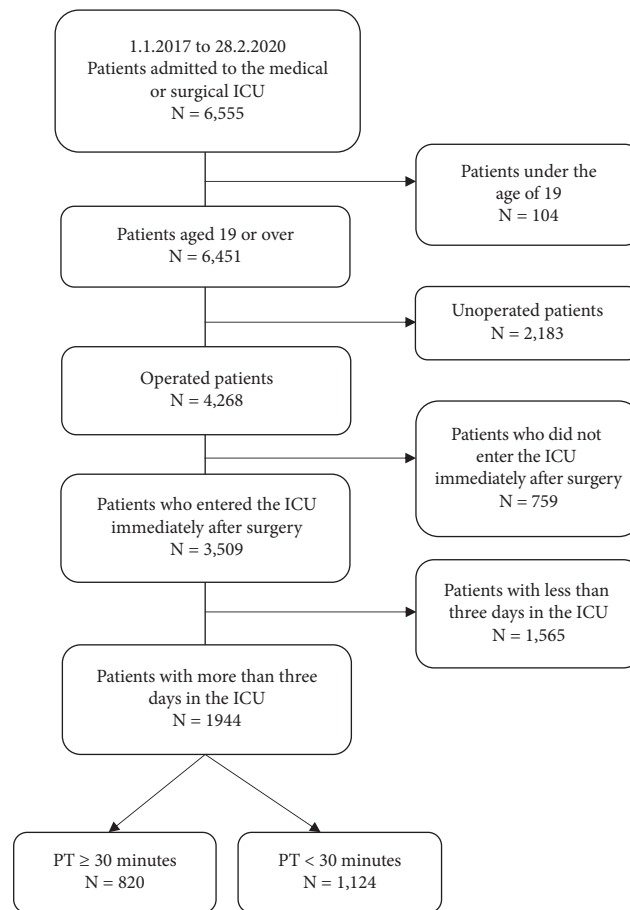

FIGURE 1: Flowchart of the selection of the study population.

complications, respiratory nursing needs score, ventilator application, restraint application, transfusion, use of narcotics, and ICU length of stay (ICU LOS).

The recovery period of surgery patients is classified into three stages: 24 hours to within 7 days, 28 to 60 days, and 6 weeks to 3 months [33]. The first stage of recovery (24 hours to within 7 days) is the acute postoperative phase and a crucial period in postoperative management. Since we speculated that the impact of surgery preparation time would lessen over time after the seven-day mark, we selected postoperative patient outcomes occurring within seven days postoperation as the outcome variables [33].

Alertness was determined based on the percentage of times the patient was found to be alert in the level of consciousness assessment (alert, confusion, drowsy, stuporous, semicoma, and coma) within seven days of being admitted to the ICU. This percentage was categorized as $\geq 50\%$ or $<50\%$. The number of nursing diagnoses related to postoperative complications was determined based on the daily average number of diagnoses over seven days of being admitted to the ICU. We selected and analyzed 60 nursing diagnoses related to postoperative complications, such as "impaired gas exchange," "electrolyte imbalance," and "risk of deficient fluid volume," from the diagnoses in use at the time at the target hospital. The daily average number of nursing diagnoses related to postoperative complications per individual was

found to be 5.75. Therefore, we categorized the study population as individuals with >5.75 diagnoses related to postoperative complications and those with ≤ 5.75 diagnoses.

The respiratory nursing needs score is the score of respiratory care needs that is measured daily on a scale from 0 to 82. The higher the score, the more respiratory care needs are evident. In this study, the study population was categorized as individuals with a score of ≤ 2 and those with a score of >2 . The reference score of 2 indicated basic respiratory care needs (such as deep breathing and assisted coughing and the use of a spirometer). Scores greater than two suggest that additional interventions are needed, such as oxygen therapy, suction, or a ventilator.

Regarding ventilator and restraint application, we categorized the study population based on whether they were applied within seven days of being admitted to the ICU. Similarly for transfusion, we categorized the study population based on whether a transfusion was performed within seven days of being admitted to the ICU. The use of narcotics was determined based on whether the narcotic analgesics listed in the medication records were administered within seven days of ICU admission. The ICU LOS was defined as the number of days spanning from ICU admission to discharge. The study population was categorized as individuals who stayed in the ICU for ≤ 7 days and those who stayed for >7 days.

2.4.3. Adjusted Outcomes. From the preoperational, intraoperational, and postoperational factors in the data source, we selected 12 adjusted variables: the body mass index (BMI), score on the American Society of Anesthesiologists Physical Status Classification System (ASA Physical Status Classification System), surgery method, systolic blood pressure (SBP), pulse, surgery time, total recovery time, score on the Acute Physiology and Chronic Health Evaluation (APACHE II), blood urea nitrogen (BUN), creatinine, creatinine phosphokinase (CPK), and lactate dehydrogenase (LDH).

The ASA score evaluates a patient's physical condition before surgery. This score was categorized as normal (I), mild systemic disease (II), severe systemic disease (III), severe systemic disease having a constant threat to life (IV), not expected to survive without the operation (V), or brain-dead patient for donation (VI).

The surgery method was categorized as surgery with scope, surgery without scope, or undefined based on the name of the operation. We classified the surgery method based on the use of a scope because using a scope has a grave impact on the surgical approach as well as the work environment of OR nurses [20, 34]. More specifically, scope-assisted surgeries require specific equipment, such as endoscopic instruments (SCOPE), CO₂, intraabdominal illumination (light cable), and specially modified instruments [34, 35]. The surgery preparation time varies owing to the process of preparing these items.

The SBP and pulse were determined based on the average SBP and pulse during surgery, respectively. The surgery time was calculated as the time starting from the time the incision was made to the time the incision was closed. The total recovery time was defined as the time from PACU admission to transfer to the patient room.

The APACHE II score indicates the severity of the disease within 24 hours of admission to the ICU. The score is calculated based on 12 items (body temperature, mean arterial pressure, blood pH, heart rate, respiratory rate, PaO₂, serum sodium, serum potassium, creatinine, hematocrit, white blood cell count, and Glasgow Coma Scale) and ranges from 0 to 71. Higher scores indicate heightened severity. Finally, among the initial blood tests conducted upon admission to the ICU after surgery, statistically significant results were observed for BUN, creatinine, CPK, and LDH.

2.5. Data Analysis. The study population was divided into two groups: the group with a surgery preparation time of 30 minutes or longer and the group with a surgery preparation time of less than 30 minutes. Chi-squared tests were performed on categorical variables, while continuous variables were analyzed using a *t*-test. Then, we performed a multiple logistic regression analysis by including the 12 adjusted variables to identify the impact of the surgery preparation time on the eight patient outcomes. These statistical analyses were performed using SAS version 9.4.

2.6. Ethical Considerations. This study was conducted after obtaining approval from the research institution's Data Utilization Review Board and Institutional Review Board

(KC23RISI0254). Personally identifiable data were deleted and replaced with numbers for safe management of the data used in this study.

3. Results

3.1. Preoperation, Intraoperation, and Postoperation Characteristics of the Study Population. Table 1 presents the results of analyzing preoperation, intraoperation, and postoperation characteristics of the study population based on the surgery preparation time. Among the study population, 820 individuals had a surgery preparation time of ≥ 30 minutes, while 1,124 had a surgery preparation time of < 30 minutes. The mean preparation time was 45.08 minutes in the ≥ 30 minutes preparation time group and 18.45 minutes in the < 30 minutes preparation time group.

The age and sex of the study population did not differ significantly between the two groups of the surgery preparation time ($p > 0.05$). In the preoperative period, the proportion of obese patients (those with a BMI of > 23 kg/m²) was higher in the ≥ 30 minutes preparation time group (48.05%) than in the < 30 minutes preparation time group (39.15%; $p < 0.001$). Furthermore, the proportion of patients with ASA classifications II and III was higher in the ≥ 30 minutes preparation time group (54.76%; $p < 0.001$). Meanwhile, the proportion of patients with ASA classifications IV and V was higher in the < 30 minutes preparation time group (51.51%; $p < 0.01$), indicating a comparatively higher degree of severity.

During the intraoperative period, the proportion of patients who underwent surgery with a scope was higher in the ≥ 30 minutes preparation time group (16.10%; $p < 0.01$), while patients who underwent surgery without scope were more in number in the < 30 minutes preparation time group (69.13%; $p < 0.01$). The proportion of patients with an SBP of ≥ 120 mmHg (39.77%; $p > 0.001$) and those with a pulse rate of ≥ 100 /minute (13.70%; $p < 0.01$) was higher in the < 30 minutes preparation time group. However, the surgery time (285.10 ± 149.22 min) was longer in the group with ≥ 30 minutes of preparation time ($p < 0.001$).

In the postoperative period, the recovery time (77.05 ± 32.59 min) was longer in the group with more than 30 minutes of preparation time ($p < 0.05$). In addition, levels of BUN (34.95 ± 28.05 mg/dL) and creatinine (2.99 ± 3.21 mg/dL) were higher in the group with less than 30 minutes of preparation time ($p < 0.001$ for both). However, CPK levels (239.07 ± 282.45 U/L) and LDH levels (725.10 ± 536.85 U/L) tended to be significantly higher in the group with more than 30 minutes of preparation time ($p < 0.001$ for both) (Table 1).

3.2. Influence of the Surgery Preparation Time on Postoperative Patient Outcomes. Table 2 presents the results of analyzing the eight postoperative patient outcomes based on the surgery preparation time. Five of the eight outcomes differed significantly based on the surgery preparation time. The ≥ 30 minutes preparation time group had a higher proportion of patients with less than 50% alertness (29.02%;

$p < 0.05$), those with a score of >2 for respiratory nursing needs (36.22%; $p < 0.05$), those who had undergone a transfusion (56.59%; $p < 0.01$), those who had been administered narcotics (62.68%; $p < 0.001$), and those who stayed in the ICU for >7 days (13.90%; $p < 0.001$).

Table 3 presents the results of the multiple logistic regression analysis. The surgery preparation time had a statistically significant effect on alertness, ventilator application, and ICU LOS. The ≥ 30 minutes preparation time group was at high risk for less than 50% alertness (OR = 1.44; 95% CI: [1.09, 1.90]) and ventilator application within seven days of being admitted to the ICU (OR = 1.32; 95% CI: [1.03, 1.70]). It was also at a high risk of staying in the ICU for more than seven days (OR = 1.69; 95% CI: [1.16, 2.47]).

4. Discussion

We included 12 adjusted variables in our analysis and found that a longer surgery preparation time lowers the rate of alertness within seven days of the operation and increases the likelihood of ventilator application and extension of the ICU LOS.

The significant decrease in the level of consciousness with an increase in the surgery preparation time is presumed to be due to the accompanying increase in the anesthesia time. General anesthesia impacts the nervous system [36] and, consequently, the level of consciousness. Therefore, shortening the surgery preparation time (and, in turn, shortening the overall anesthesia time) can affect the patient's level of consciousness after surgery. Improving the capacity of OR nurses can help shorten the surgery preparation time and improve patients' level of consciousness after surgery.

Studies have found that the "BMI, BUN, creatinine, surgery time, and surgery method, and scores on the ASA and APACHE II," prolong ICU LOS [37–42]. However, in this study, the surgery preparation time increased ICU LOS even after adjusting for these variables. Regarding surgery or medical treatment, studies have reported that the determinants of ICU LOS are primarily patients' intrinsic factors or factors on which nurses' influence is weak. This study removed the intrinsic and medical factors and confirmed that the surgery preparation time (a factor on which OR nurses' influence is the most concentrated) affects ICU LOS. Considering that the competence of OR nurses can reduce the surgery preparation time, positive patient outcomes can be expected if their competency is enhanced and thus efficient preparation time management becomes possible.

After adjusting for factors related to the patient's condition, we found that there is a higher risk of ventilator application when the surgery preparation time exceeds 30 minutes. In other words, when patient condition and surgical-related variables are similar, patients with longer surgical preparation times are at a higher risk of requiring mechanical ventilation. This finding suggests that the length of the surgery preparation time affects the occurrence of ventilator application.

Previous studies have highlighted BMI and surgery time as key factors influencing ventilator application [43–47]. However, this study revealed that the surgery preparation time, which can be controlled by OR nurses, may influence ventilator application. This finding contributes to the research on OR nursing and patient outcomes and emphasizes the importance and influence of OR nursing [48]. It also confirms the importance of OR nurses in the surgical process. From this perspective, further research on the surgery preparation time is imperative for enhancing surgical patient outcomes.

In the univariate analysis, respiratory nursing needs, transfusion, and use of narcotics differed significantly based on the surgery preparation time. However, these factors became statistically insignificant in the multiple logistic regression analysis. This result indicates that factors that have been found to influence respiratory nursing needs, transfusion, and use of narcotics in previous studies, such as BMI, score on the ASA, surgery time, and type of surgery, may act in combination [49–56]. Patients with higher scores on the ASA exhibit greater respiratory nursing needs [49]. Furthermore, as the surgery duration increases, the volume of bleeding typically increases, thereby raising the likelihood of requiring transfusions [57, 58]. This, in turn, may lead to the increased use of narcotic analgesics to manage pain. Consequently, it can be inferred that factors related to patient condition and surgical parameters exert a more significant influence on elevating the respiratory nursing needs score and the risks associated with transfusions and narcotics use, rather than the surgery preparation time. Further research is warranted on the surgery preparation time to enhance surgical outcomes for patients.

The number of nursing diagnoses related to postoperative complications did not differ significantly based on the surgery preparation time. Previous studies have indicated that patient factors influence nursing diagnoses [49]. However, no significant differences were observed in this study both before and after adjustment. This could be attributed to the fact that this study examined postoperative patient outcomes occurring within seven days of being admitted to the ICU [33]. Considering that the early stages of postsurgery are centered on preventing complications, the number of nursing diagnoses related to postoperative complications may have remained relatively constant or uniform during the 7-day period.

Finally, the surgery preparation time had no statistically significant impact on the use of physical restraint. Physical restraint is used to keep the treatment instruments in place and prevent injuries from falls or self-removal of medical devices [59]. It is recommended not to restrain patients physically, but the ICU seems to be an exception [59, 60]. It can be speculated that physical restraint was used in most cases in this study, considering that this study targeted ICU patients [61–63] and the higher likelihood of its use among patients on ventilator support.

This study investigated the impact of reducing the surgery preparation time (and, consequently, the anesthesia time) on patient outcomes. Some studies have suggested methods to reduce the surgery preparation time by focusing on the arrival time of the surgeon to the OR [18]. The

TABLE 1: Preoperation, intraoperation, and postoperation patient characteristics ($N=1,944$).

SD, standard deviation; BMI, body mass index; ASA physical status classification system (I, a normal healthy patient; II, a patient with mild systemic disease; III, a patient with severe systemic disease; IV, a patient with severe systemic disease that is a constant threat to life; V, a moribund patient who is not expected to survive without the operation); SBP, systolic blood pressure; DBP, diastolic blood pressure; surgery time, time from incision to close; dressing time, time from close to the end of anesthesia; APACHE II score, acute physiology and chronic health evaluation; BUN, blood urea nitrogen; CPK, creatinine phosphokinase; LDH, lactate dehydrogenase.

surgeon's timely arrival to the OR shortens the endotracheal tube repositioning time and ensures a quicker process of confirming the position of equipment and devices. However, other studies have argued otherwise. One study reported that the surgeon's OR arrival time does not have a significant impact on the surgery preparation time [64]. Due to this discrepancy in the findings, we could not establish clear evidence of the shortening of the surgery preparation time in relation to the surgeon's OR arrival time.

Many studies have stated that the surgery preparation time is a source of inefficiency and an aspect that needs improvement in the OR workflow, regardless of the surgical site [65–67]. However, technological advances are transforming the OR environment and surgery methods [18, 34, 68]. Now, even the same surgery method requires highly specialized competencies due to the various surgery methods used by each surgeon and department [22, 24, 65, 69–71]. The time that connects these varied surgical environments and surgery methods is the surgery

preparation time. That is, the surgery preparation time depends on the competency of the OR nurses who adapt to the changes in the OR environment and understand the various surgery methods [18].

OR nurses are unique and irreplaceable professionals in healthcare. They are responsible for guaranteeing intraoperative safety and managing and controlling intraoperative asepsis, instrument use, infection and complications, biological samples, and the technology to be employed in the OR [32]. However, the rapid changes in surgery methods and equipment increase the surgery preparation time [20]. As the surgery preparation time extends, tension intensifies during this period, resulting in an escalated workload at this stage [72]. Consequently, it makes the tasks of OR nurses more complex. Despite this, OR nursing is relatively undervalued, and the appropriate nursing cost is yet to be established [73]. Therefore, further research is needed on the surgery preparation time and specific tasks of OR nurses during this period.

TABLE 2: Results of analyzing postoperative patient outcomes based on the surgery preparation time ($N = 1,944$).

Variable	Categories	≥30 minutes	<30 minutes	χ^2/t	P value
		($n = 820$)	($n = 1,124$)

Respiratory nursing needs score (daily average)	>2	-0.0919	0.83 (0.67–1.04)
Transfusion	Yes	-0.0039	0.99 (0.80–1.23)
Use of narcotics	Yes	-0.0341	0.93 (0.74–1.20)
Number of nursing diagnoses related to postoperative complications (daily average)	>5.75	-0.0785	0.86 (0.70–1.05)
Restraint application	Yes	0.1052	1.23 (0.95–1.61)

ICU: intensive care unit; LOS: length of stay; adjusted variables: BMI (Body Mass Index), ASA (physical status classification system), surgery method, SBP (systolic blood pressure), pulse, surgery time, total recovery time, APACHE II (Acute Physiology and Chronic Health evaluation) score, BUN (blood urea nitrogen), creatinine, CPK (creatinine phosphokinase), and LDH (lactate dehydrogenase).

5. Implications and Limitations

This study has important implications for nursing management, as it examined the relationship between postoperative patient outcomes and the surgery preparation time, a period during which OR nurses play a crucial role. The findings emphasize the significance of the surgery preparation time and the need to raise awareness about the importance of OR nursing. Based on the results, we propose several policy recommendations for OR nursing management.

First, it is crucial to conduct a precise analysis of the tasks performed during the surgery preparation time, a period when most OR nursing tasks are performed. Despite advancements in surgical techniques and methods and the surgical environment, there remains a lack of discussion on the surgery preparation time. This is evident in the continued reliance on two OR nurses, regardless of changes in the surgical environment and methods, without considering variations in surgery types or complexities. Although tasks during the surgery preparation time may seem routine, they involve various elements based on theoretical knowledge

and principles. This situation indicates that despite an increase in the workload of OR nurses compared to that in the past, the current distribution system fails to reflect these changes adequately. Therefore, there is a need to reassess and adjust the work structure and processes of OR nurses. This will provide a foundation for reducing the surgery preparation time.

Second, a standardized framework must be developed for the surgery preparation time. A standardized process must be created for the surgery preparation time based on factors such as the surgical site, technique, and position to minimize errors and enhance efficiency, which would ultimately reduce the preparation time and help save costs.

Third, the OR is one of the most specialized areas within a hospital. Therefore, a lack of sufficient understanding of and proficiency in the preoperative preparation process can significantly reduce work efficiency [74–76]. Thus, OR nurses' qualifications should be redefined in terms of knowledge, skills, attitude, and experiences, and education programs must be developed to address individual educational needs [64, 76, 77]. Finally, it is essential to move away

from the traditional nursing education framework that focuses on “preoperative nursing” and “postoperative nursing.” Instead, it is important to define “intraoperative nursing” and widely communicate its importance to provide a new perspective on the role of OR nurses.

This study has some limitations. First, we did not include environmental and structural factors of ORs and the ICU because they were not included in the data source. Second, an intrinsic bias must be acknowledged, as this study was a retrospective data analysis of a single institution. Finally, the generalizability of our results is limited because the study population was limited. Nonetheless, this study offers a new perspective on the clinical aspect of surgical nursing education, serving as a turning point in explaining the importance of “quantitative” nursing beyond the existing “qualitative” nursing perspective. Such an approach aims to foster a deeper understanding of the role and education of OR nurses, emphasizing the impact of nursing during surgery on patient recovery and treatment processes. The findings of this study are expected to provide important implications for the education and practice of OR nurses.

6. Conclusion

This study shows that a surgery preparation time exceeding 30 minutes reduces the rate of alertness, prolongs the patient’s stay in the ICU, and increases the likelihood of ventilator application. Thus, the surgery preparation time should be estimated based on the surgical environment and methods from the moment a surgical schedule is confirmed to improve patient outcomes. In addition, efforts should be made to establish an efficient and reasonable management system for environmental, structural, and workforce issues to ensure that the surgery preparation time is handled efficiently according to the surgery method.

Aim. To examine the relationships among nursing professionalism, empathy, and clinical decision-making ability and the factors influencing shared decision-making awareness in hemodialysis nurses. **Background.** Self-management and treatment for hemodialysis patients are essential for maintaining health and life in daily life. In this process, shared decision-making in which patients, nurses, and medical teams participate and make decisions together has a greater impact on the health recovery and improvement of quality of life for hemodialysis patients than for any other chronic disease patients. **Methods.** A cross-sectional descriptive design was employed. Participants were 145 nurses working in the hemodialysis centers at hospitals in Seoul and Gyeonggi-do. Measures included the general characteristics of study participants, nursing professionalism, empathy, clinical decision-making ability, and shared decision-making awareness. Data were collected from May to July, 2022, and multiple linear regression analysis was used to examine the predictive factors of shared decision-making awareness. **Results.** The strongest predictor was empathy, followed by clinical decision-making ability and the level of education. The explanatory power of the final regression model was 23%. **Conclusions.** Empathy towards hemodialysis patients was an important factor influencing the shared decision-making awareness in hemodialysis nurses. **Implications for Nursing Management.** In nursing management, nursing managers or nurses should pay attention to influencing factors to improve the shared decision-making awareness of hemodialysis nurses. Empathy towards hemodialysis patients need to be reinforced to improve the shared decision-making awareness of hemodialysis nurses.

1. Introduction

In hemodialysis, self-management such as regular dialysis, fluid and dietary restrictions, drug treatment, and vascular monitoring is essential for maintaining health and life in daily life.

Disease awareness and self-care management have a positive relationship [1], and in the case of hemodialysis patients, patients with positive disease awareness are compliant with treatment [2], and the disease perception of patients who applied the shared decision-making was relatively positive, and it was found to have a positive effect on clinical indicators and patient prognosis [3]. However, since

the shared decision-making is influenced by the attitude of healthcare providers who lead the decision-making process, it is necessary to identify the shared decision-making awareness of medical personnel [4–6].

Shared decision-making is based on a shared mental model, which is the perception of, understanding of, or knowledge about a situation or process that is shared among team members through communication [7, 8]. The complexity and criticality of the current healthcare system require shared mental models to enhance safe and effective patient/client care [8, 9]. Each member's action can have an advantage in terms of efficiency, function, and strategy by using clear

communication and guidance among team members in the shared decision-making process, and by sharing an understanding of goals and expectations towards a better quality of life for the patient [7, 9–11]. In a previous study [6], it was mentioned that the role of nurses in the shared decision-making process included being a health educator, spokesman, data collector, symptom and side effect manager, information sharer, and psychological supporter. Moreover, they said that nurses play a complementary role [5, 12] to doctors in the shared decision-making process and promote shared decision-making [13]. These characteristics are suitable for playing the role of a multidisciplinary coordinator as a member of a team in the shared decision-making process, and these allow nurses to integrate the biological and social life experiences of patients with chronic diseases in the shared decision-making process [9]. Since hemodialysis nurses spend several hours a week with long-term dialysis patients during treatment, a close therapeutic relationship can be formed [14, 15] and, thus, occupies a key position in terms of patient involvement [16, 17]. Likewise, nurses' awareness of patient participation is important as they play various roles in the entire hemodialysis process [10, 18]. An important factor that can contribute to patient compliance during hemodialysis treatment is the hemodialysis nurse's attitude toward patient participation [19]. Walker et al. [20] evaluated the influence of the dialysis nurse as high as that of the nephrologist in the decision-making process for the patient's choice of renal replacement therapy. In the literature on the role of nephrology specialists in renal replacement therapy, dialysis nurses want to be involved in shared decision-making [21]. However, in South Korea, realistic hospital medical systems and diverse nursing situations exclude nurses from shared medical decision-making, and some nurses also do not know how to participate in shared decision-making [3, 22]. Therefore, it is necessary to identify the factors that affect hemodialysis nurses' awareness of the shared decision-making process for preparing a strategy to improve this decision-making process.

A literature review found that nursing professionalism [14], critical thinking tendency [23], awareness of nursing organizational culture [23], and empathy [5] were reported as the variables correlated with clinical nurses' shared decision-making awareness. Nursing professionalism is a necessary competency in the process of multidisciplinary shared decision-making [14, 24] and provides high-quality nursing through cooperation with various experts in the clinical field, and this allows nurses to perform efficient work [16, 25]. Furthermore, through the establishment of correct professionalism, patients are not excluded from decisions about treatment, but the right to know and autonomy are respected so that they can actively exercise their right to self-determination [10, 26]. Empathy refers to the necessary skills and abilities to understand and alleviate the suffering of others [24]. Empathy has a positive effect on the development of interpersonal relationships, conflict resolution, and facilitated communication [5, 27]. High empathy can provide relief and lower anxiety to patients [5, 28], and can show careful understanding that considers their emotional state and non-verbal expression by identifying their strengths and limitations

[29]. It was found that 82% of patients receiving hemodialysis treatment chose empathy as the main factor in forming a therapeutic relationship between patients and nurses [14]. In recent years, the clinical decision-making ability is regarded as an essential competency of nurses in the medical field, and the demand for it is also increasing [13, 30, 31]. Since nurses play the role of experts as patients' protectors, responsibility and decision-making ability are required of them [27]. When faced with various dilemmas related to human dignity and ethical situations on the medical site, nurses make clinical decisions based on moral behavior and critical thinking [32].

This study uses the King [33] goal attainment theory as its theoretical framework along with a review of previous literature (Figure 1). King's goal attainment theory states that in order to achieve a goal, interaction and exchange of members' perceptions, opinions, and actions are necessary. There are personal, interpersonal, and social levels of interaction and exchange. In order to achieve the goal of shared decision-making awareness, this study reflected the personal level as educational background, the interpersonal level as empathy, and the social level as nursing professional and clinical decision-making ability in interaction and exchange. Therefore, in this study, general characteristics (educational background), empathy, nursing professionalism, and clinical decision-making ability were selected as leading variables that are likely to affect the shared decision-making awareness of hemodialysis nurses (Figure 1). The purpose of this study was to examine the relationships among nursing professionalism, empathy, and clinical decision-making ability and the factors influencing the shared decision-making awareness in hemodialysis nurses.

2. Methods

2.1. Design, Sample, and Settings. A cross-sectional descriptive design was employed. This study was conducted with nurses working in hemodialysis centers at tertiary general hospitals, general hospitals, and private clinics that operate hemodialysis centers located in Seoul and Gyeonggi-do. The criteria for selecting the study subjects are as follows: (1) hemodialysis nurses with at least one year of work experience and (2) those who agreed to participate in this study. The number of subjects was calculated by using the G*power 3.1.9.4 sample number calculation program [34]. Considering the significance level (α) = 0.05, power (1- β) = 0.80, multiple regression median effect size = 0.15, and 13 independent variables, the minimum number of subjects was 131, and the dropout rate was 10%. A total of 145 subjects responded, and all responses were sufficient, so 145 copies (100%) were finally analyzed.

2.2. Instrumentation. Based on a literature review and previous research, a set of general characteristics of the study participants included age, marital status, religion, educational level, total clinical career, hemodialysis career, hospital type, position, and job satisfaction. This consisted of a total of 9 items.

FIGURE 1: Theoretical framework of this study.

The nursing professionalism scale developed by Yeun et al. [25] was used. This scale consists of 29 questions with 5 subdomains: 9 questions on professional self-concept, 5 on nursing professionalism, 8 on social awareness, 3 on nursing independence, and 4 on nursing practice. Each item is made on a Likert 5-point scale, ranging from 1 point for “strongly disagree” to 5 points for “strongly agree,” and reverse calculations were made for opposite content. A high score means that the nursing professionalism was formed positively, and the score range was 29–145. At the time of development, the Cronbach’s α of the scale was 0.92, and in the study of Cho [12], the Cronbach’s α was 0.90, while the Cronbach’s α value of 0.92 was used in this study.

The empathy scale developed by Lee [35] and modified and supplemented by Lee and Seomoon [36] was used to measure the scale of empathy. It consists of 17 questions with 3 subdomains: 8 questions on communication skills, 5 on sensitivity, and 4 on insights. Each item is made on a Likert 5-point scale, ranging from 1 point for “strongly disagree” to 5 points for “strongly agree,” with higher scores indicating a higher empathy. The score range was 17–85. At the time of scale development, Cronbach’s α , which refers to reliability, was 0.91, in the study of Seon [37], Cronbach’s α was 0.89, and in this study, Cronbach’s α was 0.84.

The clinical decision-making ability scale developed by Jenkins [38] and adapted by Baek [39] was used to measure clinical decision-making ability, and it consists of a total of 40 questions. The scale includes four subdomains: examination of alternatives and options, review of values and goals, examination of information, harmonization of new information, and assessment and reassessment of conclusions. Each subdomain consists of 10 questions. Each item is made on a Likert 5-point scale, ranging from 1 point for “strongly disagree” to 5 points for “strongly agree,” with higher scores indicating a higher clinical decision-making ability. The score range was 40–200. At the time of development proposed by Jenkins [38], Cronbach’s α , the

reliability of this scale, was 0.83, Cronbach’s α in the study of Baek [39] was 0.77, and Cronbach’s α in the study of Jang [30] was 0.85. In this study, Cronbach’s α was 0.72.

The shared decision-making awareness scale developed by Jo [22] was used to measure the level of shared decision-making awareness. It consists of a total of 34 questions with 7 subdomains: 9 questions on information sharing, 7 on establishment of a support system, 5 on duty of explanation, 4 on autonomy, 3 on catching timing, 3 on family participation, and 3 on respect for personality. Each item is made on a Likert 5-point scale, ranging from 1 point for “strongly disagree” to 5 points for “strongly agree,” with higher scores indicating a higher awareness. Score range was 34–170. At the time of tool development, Cronbach’s α , an indicator of reliability, was 0.80, and in the study of Noh [28], Cronbach’s α was 0.95. In this study, Cronbach’s α was 0.94.

2.3. Ethical Considerations. This study was conducted after obtaining approval from the Institutional Review Board (IRB no. H-2111-190-1277) of S University Hospital, and the permission from hospital institutes was obtained through the meeting with an explanation. The anonymity and confidentiality of the study were explained to the research subjects, and the study was conducted with the voluntary participation of the study participants who submitted written consent. Researchers explained that the survey will not be used for any purpose other than research and participation can be discontinued at any time during the survey, and even if participation is refused, there will be no disadvantages. Also, the results of the collected questionnaires were managed only by the researcher and were discarded according to the method set by the IRB after the study was completed.

2.4. Data Collection. The duration of data collection was from May to July, 2022. Researchers visited and explained the purpose and contents of this study to the tertiary general hospital, hospital, or private clinic where hemodialysis rooms were operated in Seoul and Gyeonggi-do. After sharing the research description and the URL of the Google survey through which one can participate, study participants fully understood the purpose of the study and voluntarily accessed the shared Google survey URL, followed the consent process, and then responded to the survey. The finished survey using a self-reporting questionnaire was collected by online, and they were managed by the authors. The time taken to finish the questionnaires was around 20–25 minutes.

2.5. Data Analysis. IBM SPSS version 26.0 (IBM Corp., Armonk, NY, USA) statistical software program analyzed the data from this study. The descriptive statistics using frequency, percentage, mean, and standard deviation analyzed the general characteristics of the study participants and the levels of study variables. The independent *t*-test, ANOVA, and Scheffe post hoc test analyzed the differences

in professionalism, empathy, clinical decision-making ability, and shared decision-making awareness according to the general characteristics of the study participants. Pearson's correlation coefficient analyzed the correlations between shared decision-making awareness and related factors. Multiple linear regression statistics analyzed and examined the factors influencing shared decision-making awareness. The statistically significant level of a p value was less than 0.05.

3. Results

The general characteristics of the study participants are shown in Table 1. As for the age distribution of hemodialysis nurses, 53 (36.6%) were under the age of 35, and 40 (27.6%) were over the age of 45. The average age was 38.89 years old. In terms of marital status, 99 (68.3%) were married; in terms of religion, 83 (57.2%) were nonreligious; and in terms of academic background, 76 people (52.4%) graduated from a four-year university, accounting for the largest proportion. Less than 10 years of clinical experience was most common with 52 (35.9%), and the average clinical experience was 14.36 years. In terms of hemodialysis nurse experience, less than 5 years was the most frequent with 55 (37.9%), and the average experience was 8.21 years. As for the type of hospital where they worked, tertiary general hospital accounted for the highest number with 82 (56%), and 117 (80.7%) were general nurses, and 97 (66.9%) responded that they were satisfied with their current workplace (Table 1).

The levels of shared decision-making awareness, nursing professionalism, empathy, and clinical decision-making ability are presented in Table 2. The mean score for shared decision-making awareness was 147.16, which indicates a high shared decision-making awareness when compared to the median value (102 points) of the score range (34–170). The mean score of nursing professionalism was 102.87, which indicates a slightly low nursing professionalism when compared to the median value (104 points) of the score range (68–140). Their mean score for empathy was 66.68, which indicates a low empathy when compared to the median value (69.5 points) of the score range (54–85). The mean score for clinical decision-making ability was 138.26, which indicates a low clinical decision-making ability when compared to the median value (142.5 points) of the score range (120–165) (Table 2).

Correlations among the study variables are shown in Table 3. Shared decision-making awareness had statistically significant, positive relations with nursing professionalism ($r=0.309$, $p<0.001$), empathy ($r=0.422$, $p<0.001$), and clinical decision-making ability ($r=0.395$, $p<0.001$). The higher the level of nursing professionalism, empathy, and clinical decision-making ability, the higher the shared decision-making awareness (Table 3).

The factors influencing shared decision-making awareness are shown in Table 4. Factors influencing shared decision-making awareness were tested on 145 hemodialysis nurses. Data were collected through questionnaires and shared decision-making awareness among the general characteristics and educational level, which showed

a significant difference and were used as predictive variables. Nursing professionalism, empathy, and clinical decision-making ability, which were independent variables that showed statistically significant differences in Pearson's correlation analysis, were also input as predictor variables, and shared decision-making awareness was set as a dependent variable. The collected data were analyzed by using SPSS 26.0. Moreover, there was no outlier larger than the absolute value of 3 when diagnosing cases, so all cases were analyzed with the input method.

First, as a result of testing the regression analysis, all assumptions were satisfied. Durbin–Watson was 1.790, which satisfied Tabachnick [40] criterion of 1.5–2.5. There was no autocorrelation of errors. Furthermore, the correlation coefficients between independent variables were all less than 0.8. As a result of testing multicollinearity by using tolerance limits and VIF values, there was no problem with multicollinearity between variables in which the tolerance limits were less than 0.1 or the VIF values were greater than 10. Then, as a result of analyzing the influence by using Cook's D plot, there was no individual with a value of 1.0 or more among the 145 nurses. In the residual analysis, the linearity and normality of the errors were confirmed with a pictogram, a normal P-P plot of regression standardized residuals, and a normal distribution table. Homoscedasticity was also confirmed as the scatter plot between the standardized residual of the dependent variable and the independent variable did not have a specific distribution, but spread evenly around 0.

After analyzing the regression model, it was found to be significant ($F=11.73$, $p<0.001$). The adjusted coefficient of determination ($AdjR^2$) was 0.23, showing an explanation power of 23%. The factor that had the greatest influence on the hemodialysis nurse's shared decision-making awareness was empathy ($\beta=0.250$, $p=0.012$), followed by clinical decision-making ability ($\beta=0.226$, $p=0.008$) and the educational level ($\beta=0.154$, $p=0.046$) (Table 4).

4. Discussion

The correlation between various study variables and factors influencing shared decision-making awareness was examined. Nursing professionalism had no direct influence on shared decision-making awareness. This is consistent with the results of previous studies [5, 23]. This is thought to be due to the result that the independence area of nursing was the lowest in the subcategories of nursing professionalism. This is because the relationship between doctors and nurses in the medical field is not a horizontal one, but a hierarchical relationship, which limits the ability of nurses to independently make decisions and fulfill their roles [8, 11, 16]. However, when nursing professionalism is established, patients can actively exercise their right to self-determination in the decision-making process during treatment by ensuring the patients' right to know and autonomy in the shared decision-making process [26, 27]. High nursing professionalism raises awareness of ethical decision-making so that nurses can become protectors in the decision-making process of vulnerable subjects, ensuring their participation

TABLE 1: General characteristics of the study participants ($n = 145$).

Variables	Categories	N	%	Mean (SD)
Age (years)	<35	53	36.6	38.89 (8.56)

in the shared decision-making [14, 41]. Through this development, we could confirm that nursing professionalism is a variable correlated with shared decision-making awareness, as in the results of previous studies [5, 12]. As nursing professionalism is constantly developed and can be

improved through training, advancement through the development and application of educational programs in clinical practice is required [16, 23]. In clinical settings, when patients are hospitalized in an emergency room and suddenly begin hemodialysis, most patients are not provided

TABLE 3: Correlations among study variables ($n = 145$).

with information about the choice of dialysis method and are unable to proceed with shared decision-making [10, 24]. A hemodialysis nurse with a high level of professionalism respects the patient's right to know, provides information that has not been provided, and shows a facilitator who helps patients choose a dialysis method appropriate for their lifestyle through shared decision-making in situations where dialysis must be maintained [12, 14].

The influence of empathy had the greatest effect on shared decision-making awareness. This supports the results of previous studies [5, 28]. Empathy ability was identified as a factor influencing the interpersonal relationship formation of nursing students [42, 43] and facilitated the communication ability of psychiatric nurses [29, 44]. Empathy works as an influencing factor in shared decision-making awareness because this process can form a therapeutic relationship among the patient, family, and healthcare provider, and is performed jointly by forming a positive interpersonal relationship [13, 27]. Moreover, empathy affects communication ability [45], and is a competency required of nurses to understand and care for patients [41, 45], which is consistent with the competency required in the shared decision-making process. The results of previous studies [5, 24] showed that nurses with high education and age showed high empathy, which is partially consistent with the results of this study. Since empathy is a capability that is enhanced by experiential training as well as educational training [44], it is considered that this result emerges because the understanding and experience of the subject could increase as age increases. Therefore, it is necessary to provide practical education and training to improve empathy and enhance shared decision-making awareness. Systemic efforts to reduce the turnover of experienced nurses with high empathy will also be required. Hemodialysis nurses with high empathic ability due to long clinical experience form therapeutic relationships with dialysis patients, enabling patients to make choices with trust in situations of therapeutic choice, and play the role of psychological supporter in the shared decision-making process [13].

Finally, the clinical decision-making ability of hemodialysis nurses was identified as a factor that influences shared decision-making awareness. Applying critical thinking to clinical practice can improve clinical decision-making ability through efficient and prudent responses [31], and make clinical decisions through ethical behavior and critical thinking [32]. Also, critical thinking is an influencing factor that strengthens shared decision-making awareness [23]. Considering these points, clinical decision-making ability

could affect the shared decision-making awareness. However, it is difficult to make a direct comparison since there is no previous study on the relationship between these two factors, so further studies will be needed. Among the subdomains of the clinical decision-making ability, evaluation and reevaluation of consequences had the highest score, while the search for alternatives or options had the lowest score, which is consistent with the results of previous studies [31]. Since there are many emergency situations due to hemodynamic instability during hemodialysis, it is difficult to spend time to investigate and select alternatives, such as emergency room nursing, and the patient's condition and outcome are evaluated after dealing with the emergency [28]. Accordingly, the evaluation and reevaluation of consequences scored the highest [32]. The area of search for alternatives or options for various problems is an important part of clinical decision-making, as well as the evaluation of results. Thus, education and training with respect to considering and selecting alternatives for each situation are required. During the process of hemodialysis, many emergency situations occur due to hemodynamic instability, and in such situations, hemodialysis nurses need high clinical decision-making ability [27, 32]. After the emergency situation is resolved, the process and results are evaluated to prepare alternatives to prevent and deal with hemodynamic instability for the patient during the next dialysis.

4.1. Study Limitations. This study is limited in the scope of sampling, targeting only hemodialysis nurses working in hemodialysis centers located in Seoul and Gyeonggi-do. Moreover, it is difficult to generalize the results of the study because only hemodialysis nurses who agreed to the survey were included even within the sampling range. Above all, since there is a large difference in the hospital environment where dialysis nurses work, reflection of this is very important, and this may be the limitation of this study.

5. Conclusions

In conclusion, nursing professionalism, empathy, and the clinical decision-making ability of hemodialysis nurses were significantly correlated with shared decision-making awareness, and empathy was the most influential factor in shared decision-making awareness as a result of the regression analysis. Awareness was influenced by the clinical decision-making ability and educational level. This study can provide basic data for the development of an intervention

program that can improve the shared decision-making awareness among hemodialysis nurses, and can contribute to patient satisfaction and self-care enhancement through active implementation of shared decision-making in the field by improving shared decision-making awareness.

6. Implication for Nursing Management

Based on this study, hemodialysis nurses are necessary to improve their empathy and clinical decision-making ability toward hemodialysis patients, whose number is rapidly increasing, while also increasing shared decision-making awareness and promoting patient participation in the process. Ultimately, this will improve the quality of clinical nursing for hemodialysis patients by promoting self-treatment, safe dialysis, and stable management of various chronic diseases, thereby improving their quality of life. Creating an environment to improve shared decision-making awareness of hemodialysis nurses and related training would be essential. Therefore, nursing managers need to pay attention to factors influencing shared decision-making awareness of hemodialysis nurses. Furthermore, it is necessary to develop an intervention program to raise shared decision-making awareness and conduct an experimental study to verify its effectiveness. This study is significant because it could provide basic data to prepare strategies to improve the shared decision-making awareness of hemodialysis nurses.

Data Availability

The data that support the findings of this study are available from the corresponding author upon reasonable request.

Ethical Approval

The study was approved by the Institutional Review Board of Seoul National University Hospital (IRB no. H-2111-190-1277).

Conflicts of Interest

The authors report no actual or potential conflicts of interest.

Authors' Contributions

Study design: JY, MS, SS; Data collection: JY, MS, SS; Data analysis: JY, MS, YC, SS; Study supervision: SS; Manuscript writing: JY, MS, SS; Statistical advice, re-writing, review, editing: JY, MS, YC, SS; Critical revisions for important intellectual content: JY, MS, YC, SS; All authors are in agreement with the content of the manuscript.; All authors gave final approval of the version to be published.

Acknowledgments

The authors would like to thank all the participants for their contributions to this study.

Background. Work engagement and patient-safety outcomes in nursing practice are critically significant. However, most previous studies evaluating antecedents of work engagement and patient-safety outcomes have used cross-sectional designs. **Aims.** To investigate the effects of job resources (organizational support and leader empowerment) and core self-evaluation on nurses' work engagement and patient-safety outcomes. **Methods.** This longitudinal study surveyed 2,618 registered nurses from 17 public hospitals in XuZhou, China. Participants completed self-report questionnaires on organizational support, leader empowerment, and core self-evaluation at baseline. Work engagement and patient-safety outcomes were collected 18 months after the baseline. The mixed linear regression and Johnson–Neyman statistical analysis were used to analyze data. **Results.** Organizational support was an outside predictor of nurses' work engagement, followed by core self-evaluation and leader empowerment. Organizational support and core self-evaluation were equally crucial for predicting patient-safety outcomes. Moreover, the positive impact of leader empowerment on patient-safety outcomes became significant when the core self-evaluation score was below 51. **Conclusions.** This study demonstrated that organizational support, leader empowerment, and core self-evaluation are important determinants of nurses' work engagement and patient-safety outcomes. **Implications for Nursing Management.** Hospital managers and nurse leaders should consider providing multiple supports to motivate staff nurses to engage in work. When nurses' core self-evaluation is low, empowering training for nurse leaders should be essential to reduce adverse patient events.

1. Background

Work engagement has stimulated constant interest as it is closely related to nurses' work effectiveness, patient outcomes, and institutional costs [1]. Work engagement is a positive, fulfilling, work-related state of mind with three fundamental dimensions: vigor, dedication, and absorption [2]. International Council of Nurses has recognized the need for nurses committed to high-quality standards and engaged in their work in the implementation of global action on patient safety and achieving universal health coverage [3]. However, the level of engagement among nurses is often reported to be low, and the COVID-19 pandemic has worsened it [4].

The literature shows that both job and individual-level resources are essential predictors of nurses' work engagement [5]. Organizational support is a kind of job resource, which provides resources, reinforcement, encouragement, and communication to employees [6]. Nurses who experience more organizational support report higher work performance and engagement levels [7, 8]. In addition, empowerment is also a precious job resource that plays a crucial role in the professional growth of nurses [9]. Leader empowerment is defined as the giving or delegation of power and authority. Several studies have shown that nurse leaders' empowering behaviors, specifically psychological and structural empowerment, positively affect nurses' work engagement [10, 11].

Personality traits such as core self-evaluation are also closely correlated with work engagement among nurses. Core self-evaluation describes an individual's evaluation of themselves and combines four core traits: self-esteem, generalized self-efficacy, neuroticism, and locus of control [12]. A significant and expanding body of research in business and psychology correlates higher levels of employees' core self-evaluation with better work engagement [13]. Previous research on nurses' personality traits and work engagement has focused on optimism, resilience, introspection, sensibility, and hardiness [14, 15]. Though limited studies have examined the effect of core self-evaluation on work engagement among nurses, studies have shown that core self-evaluation is significantly associated with burnout [16], the polar opposite of engagement. According to the Nursing Job Demands-Resource (JD-R) Model [17], adequate job resources, combined with more incredible personal strengths, increase the possibility of nurses experiencing higher levels of work engagement. However, no empirical study has explored the interaction effects of organizational support or leader empowerment and core self-evaluation on the engagement of nurses. Based on these theoretical and empirical arguments, we hypothesize the following points:

Hypothesis 1a. Organizational support will predict nurses' work engagement

Hypothesis 1b. Leader empowerment will predict nurses' work engagement

Hypothesis 1c. Core self-evaluation will predict nurses' work engagement

Hypothesis 1d. The interaction effect of organizational support and core self-evaluation on nurses' work engagement will be statistically significant

Hypothesis 1e. The interaction effect of leader empowerment and core self-evaluation on nurses' work engagement will be statistically significant

An emergent amount of evidence supports that nurses' work engagement is associated with patient-safety outcomes [18, 19]. Typical adverse patient-safety outcomes formulated by the American Nurses Association include falls, pressure ulcers, healthcare-associated infections, medication errors, patient complaints, and verbal abuse [20]. One recent scoping review estimated that a median of 10% of patients were affected by at least one adverse event [21], which led to death and high medical costs. Organizational support is known as an important resource to enhance nurses' job performance [22], which plays a central role in promoting patient safety. However, few empirical studies have directly explored the relationship between organizational support and patient-safety outcomes. Researchers have linked patient-safety outcomes to leader empowerment. A review of the literature indicates that workplace empowerment is critical for nurses to implement person-centered care and promote patient safety [23]. Correctly identifying the patient

before conducting any nursing operations can be fundamental to ensuring patient safety in hospitals. Kim and Kim found that leader empowerment was positively associated with nurses' patient identification behaviors [24].

Core self-evaluation has proven to be an essential predictor of nurses' clinical decision-making [25], which can guarantee patient safety [26]. However, no studies have directly explored the relationship between nurses' core self-evaluation and patient-safety outcomes. Furthermore, there exists a significant knowledge gap about how job resources in nursing affect patient-safety outcomes from the perspective of core self-evaluation. The following hypotheses are derived from these empirical arguments:

Hypothesis 2a. Organizational support will predict patient-safety outcomes

Hypothesis 2b. Leader empowerment will predict patient-safety outcomes

Hypothesis 2c. Core self-evaluation will predict patient-safety outcomes

Hypothesis 2d. The interaction effect of organizational support and core self-evaluation on patient-safety outcomes will be statistically significant

Hypothesis 2e. The interaction effect of leader empowerment and core self-evaluation on patient-safety outcomes will be statistically significant

In summary, research on nurses' work engagement and patient-safety outcomes has increased over the last decade. However, most existing studies used a cross-sectional design. Furthermore, significant variances in nurses' work engagement and patient-safety outcomes may occur between hospitals [27]. Previous studies did not consider this phenomenon [17], which may affect the conclusions' accuracy and reliability. Based on the "Nursing Job Demands-Resource Model" and empirical evidence, the conceptual framework of this study (Figure 1) was developed.

2. Methods

2.1. Design. An 18-month prospective design was used in this study. Demographic characteristics, organizational support, leader empowerment, and core self-evaluation were collected at baseline, and work engagement and patient-safety outcomes were collected 18 months after the baseline. Data were collected from September 2021 to March 2023.

2.2. Participants. Random cluster sampling was performed to recruit nurses from 17 public hospitals in Xuzhou, China. Fifteen wards were randomly selected from each of 17 hospitals. All registered nurses of the sampled wards were invited to participate. The inclusion criteria were (i) being employed full-time; (ii) having more than one year of nursing work experience; and (iii) currently working in direct patient care roles. The PASS 2008 statistical software

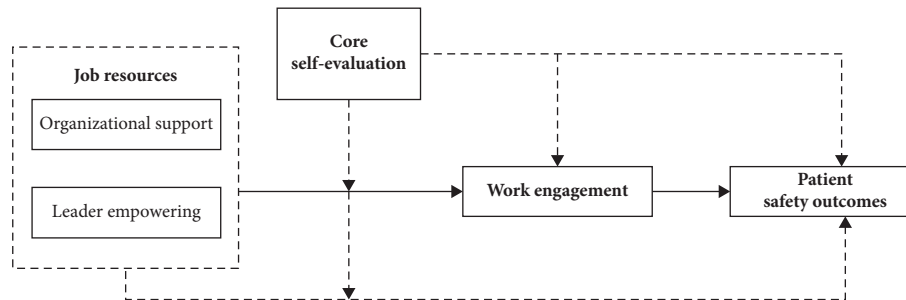

FIGURE 1: The theoretical framework of the relationship between job resources, core-evaluation, engagement, and patient-safety outcomes. A solid line indicates that the findings from the previous studies support the demonstrated relationships. A broken line indicates that no research evidence in nursing studies has demonstrated the relationships yet.

(Utah, USA) was used to calculate the sample size. A sample size of 1,067 from a population of 11,154 nurses in 17 hospitals was required based on a confidence level of 95% and a confidence interval of 3. To ensure that at least 10% of nurses in each of the hospitals participated, the target sample size was adjusted to 1,116. The final sample size of this study was 2,628, which met the minimum sample size requirement.

2.3. Data Collection. The online survey form was used to reduce response biases such as social desirability [28]. At time 1 (10 September 2021), the invitation to participate, with a link to the web-based questionnaire, was sent to eligible nurses via e-mail by the researcher. Reminder letters were sent to nonresponders 12 hours later. The same procedure was followed at time 2 (13 March 2023) by the same researcher. Only nurses who responded at time 1 were sent a time 2 survey package. At time 1, surveys were sent to 10,338 nurses and 6,234 were returned (60.3% response rate). At time 2, 2,618 nurses who responded at time 1 completed surveys (40.2% response rate).

2.4. Data Collection Tools. Web-based self-reported questionnaires were used to collect demographic characteristics, organizational support, leader empowerment, core self-evaluation, and patient-safety outcomes.

2.4.1. Organizational Support. The organizational support was measured using the Survey of Perceived Organizational Support (SPOS) [6], a 9-item single-dimension questionnaire. Participants rated items on a 7-point Likert scale ranging from 1 = “strongly disagree” to 7 = “strongly agree.” Items were added to create total scores, with increasing scores indicating higher perceptions of organizational support. SPOS is a valid and reliable instrument for Chinese nurses [29]. Cronbach’s α in this sample was 0.92.

2.4.2. Leader Empowerment. We used the Leadership Empowerment Behavior (LEB) scale to assess levels of leader empowerment [30]. The 12-item LEB scale consists of four subscales (enhancing the meaningfulness of work, fostering participation in decision-making, expressing confidence in

high performance, and providing autonomy from bureaucratic constraints). Each subscale consists of three items rated on a 5-point scale ranging from 1 = “strongly disagree” to 5 = “strongly agree,” added to create total scores. Higher overall scores suggest more leader empowerment behaviors. The LEB scale has been used by nurses with good psychometric properties [31]. Cronbach’s α in our study was 0.97.

2.4.3. Core Self-Evaluation. The Core Self-Evaluations Scale (CSES) was used to measure the core self-evaluations of nurses [32]. It consists of 12 items rated on a 5-point Likert scale (1 = “strongly disagree” to 5 = “strongly agree”). Noteworthy, six items in the CSES scale were rated in reverse order. The total score is measured by summing all items, with higher scores suggesting a better core self-evaluation. Zhang et al. have demonstrated the reliability of CSES in Chinese nurses [33]. In our study, Cronbach’s α was 0.88.

2.4.4. Work Engagement. We measured nurses’ work engagement using the Utrecht Work Engagement Scale (UWES) [2], a 17-item questionnaire comprising three subscales: vigor (six items), dedication (four items), and absorption (five items). Each item is rated on a 7-point scale (0 = “never” to 6 = “always”), with higher scores representing greater engagement. This tool has been validated and applied to Chinese nurses [34]. Cronbach’s α in this sample was 0.97.

2.4.5. Patient-Safety Outcomes. Patient-safety outcomes were measured by the Adverse Patient Events Scale (APES) [35], derived from the Nursing Quality Indicators formulated by the American Nurses Association. The APES contains six patient adverse event types: falls, pressure ulcers, healthcare-associated infections, medication errors, patient complaints, and verbal abuse. Nurses were asked to recall their experience of patient adverse events as a result of direct patient care provided by themselves over the past year. Response options ranged from 1 (never) to 7 (daily). Nurses’ assessments of patient adverse events have been utilized extensively in nursing and health care [36–38], and the APES was found to have excellent psychometric properties with Cronbach’s α of 0.93 [38]. In our study, Cronbach’s α was 0.84.

2.4.6. Demographic Variables. Sociodemographic and professional information included the age (years), gender (female, male), the highest education level (college degree or below, university degree, or above), marital status (single, married), duration of working in nursing (years), professional title (nurse, nurse practitioner, or above), and annual salary (\$).

2.5. Ethical Considerations. Institutional Review Board approval (no. KZXY-LK-20210903-026) was obtained from the researcher's hospital before commencing the study.

2.6. Strategy to Control the COVID-19 Pandemic Effects. Although the study was conducted post-COVID-19 pandemic, this crisis contingency may affect the study findings. We have taken the following measures to ensure the reliability of the results. First, all study hospitals have received unified training on the medical treatment of COVID-19 and specialized training on critical care, ensuring consistency in crisis management capabilities. Second, during the study period, there were no clusters of COVID-19 cases in the area where the study hospitals were located. Third, all study hospitals had a special ward for COVID-19 patients, and nurses from this ward were not included in this study. Fourth, we used a mixed linear model to accommodate for within-hospital correlations. In addition, the hospital hierarchy, which reflects the comprehensive strength and crisis management ability of each research hospital, was controlled in the data analysis.

2.7. Data Analysis. The first author, uninvolved in data collection and thereby unable to identify participants, conducted the entire analysis to avoid researcher bias. Data were presented as means \pm standard deviations (SDs) or n (%). Before the analysis, the histogram plot was used to determine whether the numeric variables showed a normal distribution. Next, descriptive statistics and t -tests were applied to show the distributions of demographic characteristics and the association with nurses' work engagement and patient-safety outcomes.

Because of the multilevel nested structure of the data (2618 nurses from nine different hospitals), we used a data-analysis method of mixed linear models. The dependent variables were nurses' work engagement and patient-safety outcomes at the 18-month follow-up. In Step 1, the control variables on the individual level (demographic variables that showed statistically significant in t -tests) and on the hospital level (hospital hierarchy) were entered into the regression model; in Step 2, explanatory variables (organizational support, leader empowerment, and core self-evaluation) were added; and in Step 3, the interaction effect of the explanatory variables was added. In the analysis, the hospitals were treated as random effects, and the other independent variables as fixed effects. The model fit was evaluated by degree of freedom (DF), log-likelihood (LL), and the Akaike information criterion (AIC) [39].

To explicate significant interactions, we used the Johnson–Neyman technique [40] to determine how the effect of independent variables on dependent variables varies from being significant or not based on the moderator's value. All analyses were performed using IBM SPSS (version 22.0; SPSS Inc.), with $P < 0.05$ being considered statistically significant.

3. Results

3.1. Participant Characteristics. Participants included 2,618 registered nurses recruited from 17 public hospitals. Nurses were 31.53 ± 6.98 years old with 9.69 years of nursing experience. Most were female (98.8%), and about 79% held a university degree or above. Nearly half (44.5%) of respondents had a nurse practitioner or above professional title, and only 38.3% had an annual salary of more than \$8,430.

There are statistical differences in work engagement in age, education level, marital status, work years, professional title, and annual salary (Table 1). Moreover, nurses' age, marital status, work years, and annual salary were also associated with patient-safety outcomes (all $P < 0.05$).

3.2. Longitudinal Analyses for Nurses' Work Engagement. Table 2 shows the results of longitudinal analyses for nurses' work engagement. The random effect of the variance of the hospital level was significant, indicating that nurses' work engagement varied among hospitals. In Step 1, nurses with a college degree or below ($P = 0.001$) or married ($P = 0.007$) exhibited higher levels of work engagement at the 18-month follow-up.

3.2.1. Job Resources. In Step 2, Hypothesis 1a and Hypothesis 1b were supported: greater organizational support ($\beta = 0.57$, $P < 0.001$) and leader empowerment ($\beta = 0.23$, $P < 0.001$) predicated increased work engagement when accounting for participant's age, education level, marital status, work years, professional title, salary, and hospital hierarchy. A unit improvement in organizational support was associated with an increase in work engagement score of 0.57, compared to a 0.23 increase associated with a unit improvement in leader empowerment.

3.2.2. Core Self-Evaluation. Baseline core self-evaluation ($\beta = 0.51$, $P < 0.001$) predicated 18-month work engagement when accounting for individual- and hospital-level variables (Step 2), supporting Hypothesis 1c. One unit increase in a participant's core self-evaluation score was associated with an increase in work engagement score of 0.51. Taking into account standardized effect estimates, organizational support was an outsize predictor (0.31) of nurses' work engagement, followed by core self-evaluation (0.19) and leader empowerment (0.09).

3.2.3. Joint Effects. The joint effects of core self-evaluation with organizational support ($P = 0.650$) and leader empowerment ($P = 0.310$) were insignificant; thus, the Hypothesis 1d and Hypothesis 1e were not supported. When two interaction

terms were added, the model fit became worse, with the restricted log-likelihood increasing by 14.44. Therefore, no interactions were explored in the work engagement model.

3.3. Longitudinal Analyses for Patient-Safety Outcomes. Table 3 shows the results of longitudinal analyses for patient-safety outcomes. In Step 1, nurses who were married ($P = 0.005$) or made \$60,000 a year ($P = 0.008$) reported fewer patient adverse events at 18-month follow-up.

3.3.1. Job Resources. In Step 2, higher baseline organizational support predicated fewer 18-month adverse patient events when nurses' marital status, salary, and hospital hierarchy were adjusted for. When the interaction effect of leader empowerment and core self-evaluation was added (Step 3), organizational support was also significantly associated with patient-safety outcomes ($\beta = -0.02$, $P < 0.001$), supporting Hypothesis 2a. Moreover, the effect of leader empowerment on patient-safety outcomes was statistically

Work years	-0.11 (0.16)	0.466	-0.11 (0.15)	0.477	-0.11 (0.15)	0.485
Annual salary	0.30 (0.11)	0.008	0.34 (0.11)	0.003	0.34 (0.11)	0.003
Hospital hierarchy	0.00 (0.00) ^a	—	0.01 (0.08)	0.904	0.01 (0.08)	0.945
Organizational support			-0.02 (0.01)	<0.001	-0.02 (0.01)	<0.001
Leader empowerment			-0.01 (0.01)	0.122	-0.07 (0.03)	0.012
Core self-evaluation			-0.03 (0.01)	<0.001	-0.10 (0.03)	0.001
Leader empowerment \times core self-evaluation					0.001 (0.001)	0.029
Δ Restricted log-likelihood			106.35		8.28	
Variance of hospital level	0.45 (0.19)	0.020	0.29 (0.16)	0.062	0.29 (0.16)	0.061
Residual	5.71 (0.16)	<0.001	5.45 (0.15)	<0.001	5.44 (0.15)	<0.001

Note. Beta, unstandardized effect estimate. SE, standard error. ^aThis covariance parameter is redundant and the test statistic cannot be computed.

significant ($\beta = -0.07$, $P = 0.012$) when the interaction between leader empowerment and core self-evaluation was adjusted for (Step 3), supporting Hypothesis 2b. One unit increase in leader empowerment score was associated with a decrease in patient adverse events score of 0.07, 3.5 times that due to a unit improvement in organizational support.

3.3.2. Core Self-Evaluation. Hypothesis 2c was supported: baseline core self-evaluation predicted 18-month patient-safety outcomes (Step 2), and this effect remained statistically significant ($\beta = -0.10$, $P = 0.001$) after controlling for the interaction effect of leader empowerment and core self-evaluation (Step 3). One unit increase in a participant's core self-evaluation score was associated with a decrease in patient adverse events score of 0.10. Taking into account standardized effect estimates, organizational support (-0.12) and core self-evaluation (-0.12) were equally crucial for patient-safety outcomes, followed by leader empowerment (-0.03).

3.3.3. Joint Effects. After Step 2, the interaction terms of core self-evaluation with organizational support and leader empowerment were entered. Although the former was not significantly related to patient-safety outcomes, the latter was; thus, the Hypothesis 2d was not supported but the Hypothesis 2e was supported. Compared with only entering the interaction term of leader empowerment and core self-evaluation, entering the interaction terms of core self-evaluation with organizational support and leader empowerment made the model fit worse, with the restricted log-likelihood increasing by 12.89. Therefore, only the interaction between leader empowerment and core self-evaluation was explored in the patient-safety outcomes model (Step 3). The joint effect of leader empowerment and core self-evaluation on patient-safety outcomes was significant ($\beta = 0.001$, $P = 0.029$). The results of the Johnson–Neyman analysis showed that the positive impact of leader empowerment on patient-safety outcomes became significant when the core self-evaluation score was <51 (Figure 2).

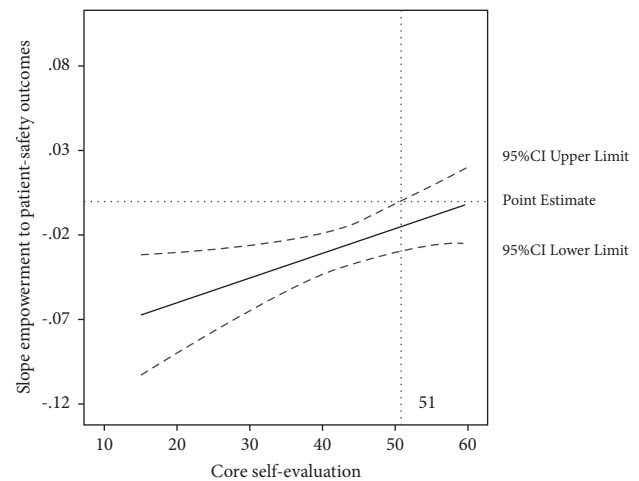

FIGURE 2: Estimated effect of leader empowerment on patient-safety outcomes moderated by core self-evaluation with Johnson–Neyman confidence bands.

4. Discussion

In this study, we clarified the effects of organizational support, leader empowerment, and core self-evaluation on nurses' work engagement and adverse patient-safety outcomes among 2,618 nurses from 17 hospitals across 18 months and examined the interaction effects. Results showed that organizational support was an outside predictor of nurses' work engagement, followed by core self-evaluation and leader empowerment. Organizational support and core self-evaluation were equally crucial for predicting patient-safety outcomes. Furthermore, the positive impact of leader empowerment on patient-safety outcomes became significant when the core self-evaluation score was below 51. These findings should enhance our understanding of the aspects of job resources and personality traits that influence nurses' work engagement and patient-safety outcomes at the hospital level.

Although research about nurses' work engagement has expanded over the decade, most published studies used cross-sectional study design. Several literature reviews identified methodological weaknesses and suggested that further research is required to decipher the antecedents of work engagement in nursing practice [17]. Our results are similar to previous findings on the positive effects of organizational support on engagement [7]. The material resources, fair rewards, and emotional encouragement from the hospital can boost the intrinsic interest of nurses in their work tasks [41]. There have been conflicting data on the impact of leader empowerment on engagement. In most quantitative studies, leader empowerment is positively associated with work engagement [10, 11]; however, some nurses reported negative perceptions of leader empowerment because communication around change initiatives was unclear and lacked feedback [42]. Our results supported that a higher level of leader empowerment leads to better work engagement in nurses. Therefore, effective communication and timely feedback for clinical nurses are essential for maintaining an empowering environment to ensure the engaged staff. Moreover, this study indicates that core self-evaluation is an independent predictor of nurses' work engagement. Several studies have demonstrated that a strong sense of self-efficacy (often described as a component of core self-evaluation) can help nurses continue to engage in clinical practice when they experience job stress and problems [7, 43]. Important information about the role of core self-evaluation in explaining work engagement among nurses needs to be included, as earlier studies almost focused on job satisfaction [44]. Work engagement has a stronger predictive value than job satisfaction since the former is closely related to nurses' care quality, patient outcomes, and institutional costs [1]. Regarding the contribution to the Nursing JD-R model [17], the present study added a new predictor-core self-evaluation. We also confirmed that leader empowerment is less strongly a predictor of work engagement than organizational support and core self-evaluation.

This study extended the finding of job resources and personality traits to outcomes other than nurses' work engagement, as we also focus on patient-safety outcomes. We found that organizational support positively affected patient-safety outcomes, which is consistent with results in existing studies [45]. Our finding suggested that adequate organizational support could improve work engagement in nurses and eventually decrease adverse patient-safety outcomes. Previous studies proved that nurses are more likely to be engaged in their work and provide high-quality care when the institutional structure and system support the care process [7, 46]. Another significant finding of our study pertains to the interaction effect of leader empowerment and core self-evaluation on patient-safety outcomes. More specifically, the benefits of high leader empowerment for fewer adverse patient events were only apparent in the context of low nurses' core self-evaluation. The possible explanation relates to the effect of leader empowerment on bridging the estrangement between leaders and employees caused by administrative hierarchy. A review noted that professional hierarchies in healthcare could increase the

chance of communication failures and potentially harm patient safety [47]. According to the core self-evaluation theory [48], core self-evaluation affects employees' thinking processes and specific appraisals of job resources. Our results indicated that nurses with lower levels of core self-evaluation had a more substantial need for leader empowerment.

4.1. Limitations. Although our study applied longitudinal design and controlled confounding variables in the mixed linear regression model, it has several limitations. First, this study should be cautiously generalized since the participants were recruited from one geographic region. The use of a convenient sample of 13 hospitals and a response rate of 60% at baseline and 40% at the 2nd time point might suggest self-selection bias, thus threatening the external validity of this study. Additional studies should be conducted in other healthcare systems with more diverse participants. Another limitation is that nurses reported patient-safety outcomes. Although nurses' assessments of patient adverse events have been utilized extensively in nursing and health care and the measures have been proven to be valid and reliable, the reliability of the results might be compromised. Future studies should collect patient adverse event data from accurate records. Third, in order to gather longitudinal data, we did not utilize anonymous questionnaires, which might lead to social desirability responses. Despite we employed different researchers for data collection and analysis, the data remained susceptible to self-reporting bias. Lastly, while multiple strategies were used to reduce the impact of the COVID-19 pandemic on the study findings, we did not directly measure the crisis management ability of study hospitals, which may undermine the credibility of the results.

5. Relevance to Clinical Practice

The results of this study indicate that nurses' work engagement is mainly predicted by organizational support. Organizational-level interventions, encompassing theory- and evidence-based practices, should be available to nurses. Given that core self-evaluation is a personality trait that predicts both work engagement and patient-safety outcomes, it may be valuable to assess the baseline attributes of the candidates and commit to ongoing training to develop positive core self-evaluation attributes. Moreover, periodic assessments of nurses' work engagement, from the perspective of staff nurses, nurse leaders, physicians, and patients, may identify solid areas and those needing improvement relative to patient-safety outcomes. Lastly, the effect of leader empowerment should be emphasized, especially when staff nurse has a low level of core self-evaluation. Helping nurse leaders develop positive empowerment practices can be a potential strategy to enhance nurses' work engagement and prevent adverse patient events. Existing literature demonstrated practical empowerment skills for nurse leaders, including giving public praise, modeling behaviors, communication skills, and coaching abilities [49].

6. Conclusion

Organizational support, leader empowerment, and core self-evaluation significantly influenced nurses' work engagement and patient-safety outcomes. Although knowledge about the relevance of nurses' work engagement is accumulating, the present study confirmed the causality of relationships between the variables by longitudinal follow-up. We hope this study can provide evidence-based guidance for hospital managers to improve the engagement of nurses. Moreover, given the interaction effect of core self-evaluation and leader empowerment on patient-safety outcomes, empowerment training for nurse leaders should be an essential component of further interventions aiming to improve patient-safety outcomes when nurses have low core self-evaluation.

Introduction. Nosocomial infections are an integral part of health care services, posing a threat to both patients and medical staff. The duty and role of nursing staff is to prevent nosocomial infections in every hospitalized person. **Material and Methodology.** The study involved 635 nurses working in various surgical and conservative wards. The technique used was the author's questionnaire, which contained 30 questions and was divided into three components. **Results.** The level of knowledge among the surveyed nurses was at a sufficient level for more than half of the total tested population, and its level was influenced by two variables: the specialization held and the level of education. Nurses working in medical wards have a higher level of knowledge in the area of basic concepts related to nosocomial infections, and people who use specialist medical literature and participate in specialist courses have a sufficient level of knowledge. The shortest time since the last training results in a higher level of knowledge and a higher level of knowledge in the area covering the basic concepts of nosocomial infections. The most frequently selected issues on which nurses would like to expand their knowledge were post-exposure procedures and methods of monitoring nosocomial infections. **Conclusions.** The knowledge of the nursing staff in the field of nosocomial infections is diverse, and its main determinants are specialization, education, and age. A sufficient level of knowledge among the respondents is conditioned primarily by the use of specialist literature and participation in specialist courses, which determine both the scope and area of knowledge on nosocomial infections.

1. Introduction

Nosocomial infections are a challenging problem in modern medicine, occurring as adverse events in connection with the provision of health services [1]. They are a therapeutic

encounter, an epidemiological problem, but also an economic problem due to the high costs mostly associated with prolonged stays of patients in hospitals [2]. The hospital environment is a favorable place for the occurrence and spread of infections both in the group of patients and

medical staff [3]. The literature on the subject emphasizes the long-known fact that nosocomial infections are an inseparable part of the treatment process, while the hands of the staff are the most important vector of transmission of microorganisms in the group of hospitalized patients. Already in the 1990s, the Centers for Disease Control and Prevention (CDC) showed that proper hand hygiene is the most effective, simplest, and, at the same time, cheapest way to prevent nosocomial infections [4]. Nosocomial infections may occur among patients treated both in conservative and surgical wards [5]. Frequently, nosocomial infections undermine the results of treatment for the underlying disease and prolong the period of hospitalization for the patient, thus creating a risk of losing their job and adversely affecting their mental health. Nosocomial infections can also lead to the death of the patient, which may result in serious legal consequences [6]. The effects of nosocomial infections affect not only the individual patient but also the entire society by affecting the cost of health premiums [7].

Reducing the frequency of nosocomial infections is a complex process, depending on several key elements: knowledge of nosocomial infections, knowledge of procedures and their observance, proper hospital hygiene, which translates into proper interruption of pathogen transmission, as well as properly applied rules of asepsis, which is crucial in preventing infections in people who underwent surgical procedures [8]. These activities are labour-intensive, tedious, and oblige us to constantly recreate the correct patterns of preventive behavior [9]. Medical personnel should have optimal qualifications, both theoretical and practical, regarding the procedures performed [10]. The largest professional group in hospitals, and at the same time the one that has the most frequent contact with patients, is the nursing staff. Therefore, they are required to take a responsible attitude at every stage of patient care, i.e., during the diagnosis of the disease, treatment planning, as well as the entire diagnostic and therapeutic process. Hygiene, asepsis, antisepsis, and work organization procedures functioning in hospitals must be very well known and performed with due diligence. Nurses' knowledge of nosocomial infections and adherence to procedures while performing nursing activities is an overriding factor that must translate into conduct in their daily work [11, 12].

Many studies indicate that there are significant gaps between scientific knowledge in the field of nosocomial infections and its practical implementation in everyday hospital practice. Another problem is the failure to comply with procedures that prevent nosocomial infections, which leads to the health risks of both hospitalized patients and medical personnel [13]. Nursing staff should have extensive knowledge of nosocomial infections, especially in the field of prophylaxis, and knowledge and competences should be constantly consolidated, updated, and based on scientific evidence [14]. Education focusing only on the transfer of theoretical knowledge is not very effective and insufficient to change behavior. Prevention and control of nosocomial infections is most effective with a multimodal strategy [15]. Indeed, a multimodal strategy to improve hand hygiene

compliance was initially approved and released by WHO in 2009. The approach uses educational tools and programs, supervision and control, active staff participation, and leadership commitment to infection control [16].

In order to acquire the appropriate skills for the prevention and control of nosocomial infections, nursing staff must undergo appropriate education and training that combine theory with clinical practice. Healthcare facilities must ensure that education correlates with the current needs of the nursing staff. Nursing staff should have time set aside for training and educational events and should be supported by their employers in applying their knowledge in practice. Internal training should be carried out by qualified persons with medical education, experts in the field of nosocomial infections, and nurses who understand the problems and needs of nurses in this area [14].

1.1. The Aim of Study. The main objective of the study was to assess the state of knowledge and education needs of nursing staff on nosocomial infections among nurses working in hospitals in the city of Kielce.

2. Materials and Methods

2.1. Variables and Their Pointers. The independent variables and their indicators were socio-demographic factors, i.e., gender (female, male), age (under 30, 31 to 39, 40 to 49, over 50), education (medical secondary school, medical vocational, higher professional bachelor of nursing, vocation master's degree in nursing), work experience (up to 10 years, from 10 to 20 years, over 20 years), specialization (yes or no), and place of work (non- or surgical ward). The dependent variable in the conducted study was the knowledge of the nursing staff about nosocomial infections, while the indicator for the adopted variable was the respondents' answers to the questions included in the questionnaire. The ranges for the variables were selected based on the analysis of similar studies on this topic.

2.2. Population and Sample of the Study. The number of nursing staff in the Świętokrzyskie Voivodeship is 5,290 people. There are 20 hospitals in the entire province. These are 1st, 2nd, and 3rd degree hospitals, oncology and pulmonology hospitals, and nationwide hospitals. There are five hospitals in the city of Kielce. Two first-level hospitals: Kielce Hospital of St. Aleksandra -Limited Liability Company and Świętokrzyskie Center for Mother and Newborn -Specialist Hospital in Kielce. One tertiary hospital is the Provincial Combined Hospital in Kielce. There is also one state hospital: the Independent Public Health Care Center of the Ministry of Interior and Administration in Kielce, and one oncology hospital: the Świętokrzyskie Oncology Center. The list of all hospitals and the number of nurses in the city of Kielce was prepared on the basis of data from the National Health Fund. The list of all hospitals in the Świętokrzyskie Voivodeship was prepared on the basis of data from the National Health Fund.

The research was carried out in all hospitals in the city of Kielce, except the Świętokrzyskie Center for Mother and Newborn - Specialist Hospital in Kielce, because mainly midwives work in this hospital. Among all medical staff working in hospitals, the focus was exclusively on nurses because nursing staff have the most frequent contact with patients and play a key role in the prevention of nosocomial infections.

Participation in the study was offered to all nurses who worked in the hospitals participating in the study. When selecting the sample for the study, the sample size calculator of the statistical program STATISTICA version for Windows 13.1 TIBCO Software Inc. was used. – StatSoft, Poland, with a 95% confidence interval. This made the sample representative. Based on data on the number of people working in the city of Kielce, the minimum group of nursing staff that should be included in the study was 311 people.

2.3. Research Methods and Tools. In order to achieve the goal set in the planned study, the diagnostic survey method was used. The survey questionnaire was developed based on the analysis of many similar studies, in which the researchers also used their own questionnaires to assess the knowledge of medical staff. Most research works on this problem are based on proprietary surveys, and such a survey was also used in the presented study [17–19].

The technique used was the author's questionnaire, which contained 30 questions and was divided into three components. The first part contained 6 questions and concerned sociodemographic data; the second part included 20 questions related to issues testing knowledge about nosocomial infections, while the last part included 4 questions concerning training in acquiring knowledge about nosocomial infections.

The tool prepared in this way was validated. Validations were carried out before the actual examination on a group of 294 nurses. Cronbach's alpha was 0.751, which proves the reliability of the tool - a self-designed questionnaire, which included questions on the state of knowledge in the field of nosocomial infections.

2.4. Data Collection Method. Based on data on the number of nurses working in the city of Kielce, the minimum number of respondents that should be included in the study was determined to be 311 people, but ultimately a larger research group of 635 people was studied. This resulted in the surveyed sample being representative. The surveys were distributed and collected from March to September 2022, and the questionnaire was distributed to various departments by the authors.

2.4.1. Data Analysis. While examining the state of knowledge and the need for education of the nursing staff on nosocomial infections, 20 statements were identified that determined its overall indicator. The answers given by the respondent were required to be classified as correct or incorrect. Each correct answer was assigned a value of 1, and

0 points for an incorrect answer. Then, the points were summed up, and the maximum number of possible scores was 20.

The statistical methods used in the work depended on the types of variables analyzed. For qualitative variables, i.e., gender, type of department, specialization, age, education, or work experience, the distribution (n) and frequency (%) are given, and to verify the independence of variables determining the level and state of knowledge, the χ^2 test was used, or, in the case of a small number, the least numerous classes ($n < 5$) χ^2 test based on maximum likelihood functions (NW). The χ^2 independence test is based on the comparison of observed and expected numbers (the expected numbers are determined assuming that the null hypothesis is true). For quantitative variables (raw values of the level of knowledge), location measures are provided: median (Me), lower quartile (Q1), and upper quartile (Q3), and the lowest (min) and highest (max) values of the examined parameter are indicated.

Searching for an answer to the research problem, how the level of knowledge regarding hospital infections develops (numerical values - raw indicator) depending on selected sociodemographic parameters or the type of ward (medical or surgical), differences in the distribution of the examined parameter were verified using the nonparametric *Mann-Whitney U test* (when comparing two independent groups) or using the *Kruskal-Wallis ANOVA* rank test (when comparing more than two independent groups). Subsequently, if the null hypothesis was rejected in favor of an alternative hypothesis for these tests (statistic value of a given test $p < \alpha$ for more than two independent groups), multiple comparisons of the mean ranks for all samples (post hoc) were performed to determine a pair of variables for which the distribution of the examined parameter was statistically significantly different. *Spearman's rho* correlation analysis was used to determine the relationship between ordinal variables (qualitative variables) and raw numerical values between the studied variables. Logistic regression analysis was used to determine the predictors influencing the level and sources of the respondents' knowledge and participation in specialized courses. The construction of the model was preceded by a preliminary selection of predictors by assessing their quality using Crammer's V coefficient. At this stage, some of the predictors were rejected, and then the sequential construction of the logistic regression model began. For this purpose, forward stepwise regression was used, and the significance of the difference between subsequent sequentially built models was assessed using the LR test (likelihood ratio). The goodness of fit of the model was verified using the Hosmer-Lemeshow test. Then, an ROC curve was constructed for the same pairs of variables, which was used to assess the compliance of the studied factors resulting from the model with the actual indications. The area under the ROC curve was calculated, denoted as AUC (area under curve), which is a measure of the goodness of the model. The Youden Index was used to determine the cut-off point for raw numerical values and to determine the sufficient level of knowledge of respondents regarding nosocomial infections.

The selected significance level of $\alpha = 0.05$ was adopted in the work. The data was collected in an Excel spreadsheet belonging to the MS Office package by Microsoft. Statistical analysis was performed in STATISTICA version for Windows 13.1 TIBCO Software Inc. – StatSoft, Poland. Data are presented in the form of tables and figures.

2.4.2. Characteristics of the Study Group. Among the respondents, the majority were women (94.00%), aged up to 30 years (32.30%), and had master's degrees (58.40%). More than half of the respondents had no specialization (60.00%), their work experience was up to 10 years (43.50%), and a larger number of nursing staff worked in surgical departments (55.00%) (Table 1).

3. Results

3.1. Sociodemographic Factors Affecting the Level of Knowledge among the Respondents. By examining the state of knowledge and the need for education of nursing staff on nosocomial infections, 20 statements were identified in three thematic areas that determined its overall index. The first area covered the basic concepts of nosocomial infections and consisted of 6 factors. The second area concerned issues in the field of infection/microbiology with particular emphasis on microbiological diagnostics, and also included 6 factors. The third and last area concerned the methods of preventing nosocomial infections and included 8 elements that influenced the assessment of the state of knowledge.

The answers given by the respondents had to be classified as correct or incorrect. Each correct answer was assigned a value of 1, and 0 for an incorrect answer. Then, the points were summed up, and the maximum number of possible points received was 20. In this approach, only correctly given answers were assessed and interpreted, which allowed for a good differentiating power of the respondents into groups with a different level of knowledge in the discussed area.

Subsequently, it was determined to what extent sex, age, education, specialization, and work experience affect the level of knowledge of nurses regarding nosocomial infections.

Comparisons of raw numerical values were made for selected sociodemographic variables. It was found that the level of knowledge about nosocomial infections was affected by the specialization, education level, and age of the surveyed nurses (Table 2).

On the basis of the raw numerical results, the general index of knowledge of the subjects regarding nosocomial infections was normalized. For this purpose, a dichotomous variable (0, 1) was created, where 0 means an insufficient level of knowledge and 1 means a sufficient level of knowledge.

The standardized qualitative variable defined in this way allowed us to conclude that the insufficient level of knowledge was present in 216 (34.02%) and sufficient in 419 (65.98%) of the examined nurses (Figure 1).

TABLE 1: Detailed characteristics of the study group of nurses.

Sociodemographic data		n	%
Sex	Woman	597	94.00
	Man	38	6.00
Age	Up to 30 years	205	32.30
	From 31 to 39 years	138	21.70
	From 40 to 49 years	142	22.40
	Over 50 years old	150	23.60
Education	Medical highschool	49	7.70
	Medical professional study	49	7.70
	Higher professional (bachelor of nursing)	166	26.10
	Higher master's nursing	371	58.40
Specialization	Yes	255	40.00
	No	380	60.00
Seniority	Up to 10 years	276	43.50
	From 10 to 20 years	126	19.80
	Over 20 years old	233	36.70
Branch type	Conservative	285	45.00
	Treatment	350	55.00

To define the state of knowledge among the surveyed nurses, the Youden Index was used (AUC = 0.537, CL 95% 0.438–0.636). The cut-off point obtained for the study group, resulting from raw scores is 14 points out of 20 possible (which is 70.00% of correct answers) (Figure 2).

The assessment of knowledge in the field of nosocomial infections (a dependent variable in the logistic regression model) was defined as a dichotomous variable with two variants: sufficient [1] and insufficient (0). The construction of the model was based on forward-step regression, and the significance of the difference between successive, sequentially built models was assessed using the LR test (likelihood ratio).

Based on the estimated logistic regression, it can be concluded that the chance of having higher knowledge in the field of nosocomial infections is 1.5 times higher among nurses with specialization (OR = 1,489; 95% CI: 1,050–2,112; $p = 0.026$) than among respondents who do not have additional competences. Another determinant is the level of education - the chance of having sufficient knowledge about nosocomial infections decreases when the respondents graduate from medical high school (OR = 0.415; 95% CI: 0.294–0.998; $p = 0.004$) and medical vocational studies (OR = 0.532; 95% CI: 0.294–0.998, $p = 0.049$). In the case of respondents with vocational education (Bachelor of Nursing), the level of knowledge is at a similar level compared to people with higher education (Table 3).

The value of the Hosmer–Lemeshow statistic is 2,442, with a value of $p = 0.295$, which proves a significant fit of the logistic regression model. Based on the analysis of the area under the ROC curve, it can also be concluded that the model is moderately fit to the data (area is AUC = 0.605) (Figure 3) and has a moderate predictive power resulting from the obtained plots of sensitivity and specificity (specificity) for various levels probabilities.

TABLE 2: The level of knowledge of the respondents (raw numerical values) due to selected sociodemographic factors and the type of ward as a place of work.

Variables	<i>n</i>	Me	Q1	Q3	Min	Max	<i>p</i> value
Generally	635	15	3	20	13	16	—
Woman	597	15	13	16	3	20	0.437 ^A
Man	38	14	12	16	5	18	
Conservative	285	15	13	17	6	20	0.016 ^{A*}
Treatment	350	15	12	16	3	19

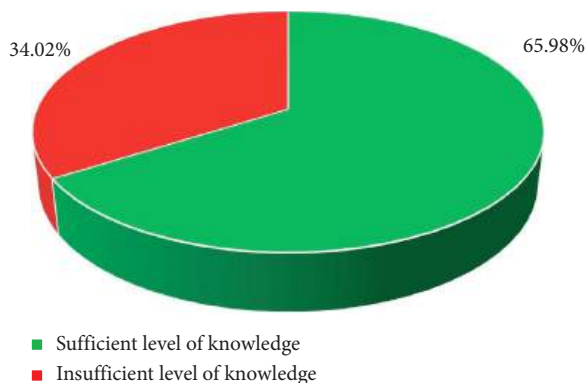

FIGURE 1: The level of knowledge of the surveyed nurses regarding nosocomial infections normalized results.

3.2. Sources of Knowledge Affecting the Level of Knowledge among the Respondents. The level of knowledge among the respondents is affected by such factors as the level of education or having additional competences in the field of specialization. Factors that can also modify (differentiate) it include internal training in the workplace, scientific conferences, specialist courses, webinars and online training, specialized medical literature, and media such as television, the Internet, and nonmedical press.

Using logistic regression, it was determined which sources had the greatest impact on the level of knowledge of the respondents (dichotomous variable) regarding hospital infections. For this purpose, forward stepwise regression was used in accordance with the procedure described when creating the model in the previous section.

Based on the estimated logistic regression, it can be concluded that the chance of having sufficient knowledge in the field of nosocomial infections is 1.6 times higher among

FIGURE 2: Youden index for the raw indicator of knowledge in the field of nosocomial infections in the group of surveyed nurses.

nurses who use specialist medical literature (OR = 1,612; 95% CI: 1,068–2,432; *p* = 0.023) and take part in specialist courses (OR = 1,613; 95% CI: 1,007–2,581; *p* = 0.047). This type of extension (supplementation) of professional competences determines a higher standardized knowledge index (Table 4).

The value of the Hosmer-Lemeshow statistic is 1,172, with a *p* value = 0.556, which proves a significant fit of the logistic regression model. Based on the analysis of the area under the ROC curve, the model is also moderately fit to the data (area is AUC = 0.572) (Figure 4) and has a moderate predictive power, resulting from the obtained plots of sensitivity and specificity for different levels of probability.

TABLE 3: Predictors affecting the level of knowledge of the surveyed nurses in the field of nosocomial infections.

Variable -reference variant	Estimation of the logistic regression parameter	OR (95% CI)	<i>p</i> value
Free expression	0.717	2.048 (1.568–2.676)	0.001

Variable -reference variant	Estimation of the logistic regression parameter	OR (95% CI)	<i>p</i> value
Free expression	0.472	1.603 (1.320–1.948)	0.001
Specialized medical literature	0.477	1.612 (1.068–2.432)	0.023
Specialized courses	0.478	1.613 (1.007–2.581)	0.047

FIGURE 4: The plot of the ROC curve for the logistic regression model is moderately matched to the sources, i.e., specialist medical literature and specialist courses affecting the level of knowledge of the surveyed nurses in the field of nosocomial infections.

3.3. Time since the Last Training and the Level of Knowledge among the Respondents. Participation in training is an important factor influencing the level of knowledge in the field of nosocomial infections. Searching for a relationship between the time that has elapsed since the last training and the state of knowledge in the field of nosocomial infections in the respondents, the variable defining the condition in question was coded in the form of ranks. The highest rank of "5" was defined as the longest time since the last training—three years and more, "4" more than two years ago, "3" two years ago, "2" a year since the last training, and "1" was assigned for the shortest time—in current year.

Using correlation analysis (Spearman's rho), a relationship was sought between time and general knowledge and its individual areas (raw numerical index) regarding hospital infections. A statistically significant relationship was found: the higher the index of general knowledge ($r = -0.080$; $p = 0.044$) and knowledge for area I ($r = -0.081$; $p = 0.041$), the shorter the time since the last training. The subjective assessment of the respondents' own knowledge also increases ($r = -0.183$; $p = 0.001$) (Table 5).

3.4. Areas of Knowledge Affecting the Increase of Competences among the Respondents. Raising professional competence is an important factor influencing the level of knowledge about nosocomial infections. New technologies and solutions force the need for continuous improvement. The respondents indicated the areas of training and courses covering issues in terms of the possibility of infections in hospital wards, including: hand hygiene, use of personal protective equipment; disinfection and sterilization; postexposure procedure; preventing nosocomial infections by properly performing nursing procedures, i.e., caring for a patient with a urinary catheter, central catheter, changing dressings, toileting a bedridden patient; ways to monitor nosocomial infections; development of epidemic outbreaks, and the principles of rational antibiotic therapy.

The need to increase competence in the field of nosocomial infections was determined using logistic regression predictors. The dependent variable in the model was the willingness to participate in specialist courses and was defined as a dichotomous variable with two variants: yes (1) and no (0). The construction of the model was based on forward step regression, and the significance of the difference between successive, sequentially built models was assessed using the LR test (likelihood ratio).

The scope of content affecting the increase in competences has been presented in the form of a model in the table below (Table 6).

Based on the estimated logistic regression, it can be concluded that people declaring the improvement of their knowledge on nosocomial infections in the form of specialist courses will more often indicate the need to improve qualifications in the area of postexposure management (OR = 3,245; 95% CI: 2,096–5,025; $p = 0.001$) and monitoring nosocomial infections (OR = 1,906; 95% CI: 1,215–2,990; $p = 0.005$) compared to those who did not indicate this form of improvement (Table 6).

The value of the Hosmer–Lemeshow statistic is 5,750, with the value $p = 0.452$, which indicates a significant model of fit of the logistic regression model. Based on the analysis of the area under the ROC curve, it can also be concluded that the model is well fitted to the data (area area is AUC = 0.684) (Figure 5) and has good predictive power resulting from the obtained sensitivity and specificity plots for different levels of probability.

3.5. General State of Knowledge of the Respondents in the Field of Nosocomial Infections. By checking the state of current knowledge of the nursing staff on nosocomial infections, three thematic areas were defined: the basic concepts of nosocomial infections; the microbiology of infections, including issues related to microbiological diagnostics; and ways to prevent nosocomial infections.

The knowledge of the nursing staff regarding nosocomial infections was checked using a standardized index. The general level of knowledge did not turn out to be statistically significantly differentiated by the type of ward ($p = 0.993$). However, it should be noted that an insufficient level of knowledge was found in every third respondent from the conservative and surgical ward (97; 34.04% vs 119; 34.00%). In the case of area, I concerning basic concepts in the field of nosocomial infections, a statistically significantly higher level of knowledge was found in people working in medical wards ($p = 0.031$). The level of knowledge for area II, microbiology of infections, including issues related to microbiological diagnostics ($p = 0.069$) and for area III, methods of preventing nosocomial infections ($p = 0.625$), turned out to be at a similar level, where only every second person surveyed was at the level of sufficient. Existing deficiencies in the professional competences of nurses and male nurses were found (Table 7).

The first area covered the basic concepts of nosocomial infections, which consisted of 6 statements covering the following issues: definition of nosocomial infection, system of preventing and combating nosocomial infections, clinical forms of nosocomial infections, definition of endo- and exogenous infections, antibiotic therapy, and selected ways of preventing nosocomial infections (procedures after-exposure).

Statistically significantly more often ($p = 0.001$) the correct definition of nosocomial infection was indicated by the respondents from medical wards (228; 80.00% vs 240; 68.57%). They defined nosocomial infection as any infection that was not in the incubation phase at the time of admission to the hospital, and symptoms occurred 48–72 hours after admission to the hospital or after discharge from the hospital within a period not longer than the longest incubation period. Every fifth person (57; 20.00%) working in conservative wards and every third (110; 31.43%) in surgical wards incorrectly defined nosocomial infection, defining it most often as any infection that was found during the patient's hospital stay and was caused by multidrug-resistant microorganisms present in the hospital environment.

TABLE 5: Relationship between the time since the last training and particular dimensions of knowledge about nosocomial infections.

Time since last training a:	Spearman's rho	$t(N-2)$	p value
Raw indicator of general knowledge	-0.080	-2.017	0.044*
Raw knowledge index: area I	-0.081	-2.049	0.041*
Raw knowledge index: area II	-0.052	-1.316	0.188
Raw knowledge index: area III	-0.039	-0.977	0.329
Subjective assessment of the state of knowledge	-0.183	-4.673	0.001*

* $p < \alpha$; $\alpha = 0.05$ a statistically significant relationship was found.

TABLE 6: Predictors affecting the level of knowledge of the surveyed nurses in the field of nosocomial infections.

Variable -reference variant	Estimation of the logistic regression parameter	OR (95% CI)	p value
Free expression	-2.022	0.132 (0.099-0.177)	0.001
Postexposure procedures	1.177	3.245 (2.096-5.025)	0.001
Methods of monitoring nosocomial infections	0.645	1.906 (1.215-2.990)	0.005

FIGURE 5: The plot of the ROC curve for the logistic regression model is moderately fitted to the predictors, i.e., postexposure management and methods of monitoring nosocomial infections, affecting the level of knowledge of the surveyed nurses in the field of nosocomial infections.

TABLE 7: The general state of knowledge of the surveyed nurses in the field of nosocomial infections.

Area	Together ($n = 635$; %)	Conservation ward ($n = 285$; %)	Treatment department ($n = 350$; %)	p value*
General knowledge about nosocomial infections				
Sufficient	419 (65.98)	188 (65.96)	231 (66.00)	0.993
Insufficient	216 (34.02)	97 (34.04)	119 (34.00)	
Area I: basic concepts of nosocomial infections				0.031**
Sufficient	376 (59.21)	182 (63.86)	194 (55.43)	
Insufficient	259 (40.79)	103 (36.14)	156 (44.57)	
Area II: microbiology of infections, including issues related to microbiological diagnostics				0.069
Sufficient	280 (44.09)	137 (48.07)	143 (40.86)	
Insufficient	355 (55.91)	148 (51.93)	207 (59.14)	
Area III: ways to prevent nosocomial infections				0.625
Sufficient	292 (45.98)	128 (44.91)	164 (46.86)	
Insufficient	343 (54.02)	157 (55.09)	186 (53.14)	

The asterisks indicate as follows: *Test χ^2 , ** $p < \alpha$; $\alpha = 0.05$ statistical significance was found.

Statistically significantly more often ($p = 0.001$) the respondents from medical wards (278; 97.54% vs 315; 90.00%) correctly defined the procedure for implementing and ensuring the functioning of the system for preventing and combating nosocomial infections as mandatory for

all hospitals, imposed by law. The most frequently selected incorrect answer was the statement that the procedure in question is obligatory for clinical, specialist, and provincial hospitals, and voluntary for powiat hospitals.

Every second person, both working in conservative and surgical wards ($p = 0.206$), was able to correctly determine that the most common form of clinical nosocomial infection is urinary tract infection (152; 53.33% vs 169; 48.29%). The incorrect answer indicated by the subjects in both groups was that it is pneumonia. It was found that the respondents did not have sufficient competence (knowledge) in the discussed area.

The correct definition that endogenous infections are caused by microorganisms from the patient's own physiological flora (natural microbiota) was more often indicated by the respondents working in conservative wards than in surgical wards (207; 72.63% vs 231; 66.00%), but this difference turned out to be statistically insignificant ($p = 0.067$). Every third respondent incorrectly indicated the source of these infections, pointing to the environment of a given hospital/patient's surroundings.

The next area covered knowledge in the field of antibiotic therapy and the determination of therapy, which consists in selecting the drug in accordance with the identification of the pathogen and determining its drug susceptibility. The vast majority of respondents answered the question correctly, pointing to targeted therapy (269; 94.39% vs 326; 93.14%, $p = 0.521$). Combination therapy was the incorrectly chosen answer.

According to the respondents, the potential source of HBV, HVC and HIV infection is blood and any biological material containing blood and semen, pre-ejaculate, and vaginal discharge. This is the correct answer, which was indicated equally often ($p = 0.383$) by the respondents from the conservative and surgical wards (251; 88.07% vs 300; 85.71%). Incorrect answers included statements that only blood and any biological material containing blood are such a source (Table 8).

The second area (6 items) focused on the microbiology/infections, taking into account issues in the field of microbiological diagnostics and etiological factors of nosocomial infections.

The respondents indicated *Staphylococcus aureus*, *Escherichia coli*, and *Pseudomonas aeruginosa* as the most common etiological factor of nosocomial infections for the entire hospital, where statistically significantly more often ($p = 0.048$) correct indications were found in people working in medical wards (218; 76.49% vs 243; 69.43%). The most frequently indicated incorrect answer was that this agent is *Streptococcus pyogenes*, *Klebsiella pneumoniae*, and *Acinetobacter baumannii*.

According to the respondents, the microorganism that most often contributes to the occurrence of hospital diarrhea in adults is *Clostridioides difficile*. The frequency of correct indications in both study groups (247; 86.67% vs. 291; 83.14%) was statistically insignificantly differentiated ($p = 0.220$). The most common incorrect answer in the discussed area was the indication of *Escherichia coli* EPEC (enteropathogenic strains of *Escherichia coli*).

According to the respondents, the most common ways of transmission of *Staphylococcus aureus* in the hospital environment are the hands of medical personnel (202; 70.88% vs 236; 67.43%, $p = 0.350$). Unfortunately, every third

respondent could not correctly indicate the routes of its transmission, pointing to surgical tools. The hands of nursing staff play an important role in the transmission of microorganisms and thus contribute to the spread of nosocomial infections.

If sepsis is suspected in a patient with a central venous line, blood should be collected from the central line and 2 separate peripheral lines for microbiological testing. This procedure was indicated only by every second respondent (131; 45.96% vs 172; 49.14%, $p = 0.425$). The others pointed to an incorrect operation taking blood from a central venous line and one peripheral venous line. This allows for the conclusion that knowledge in the discussed area is insufficient.

The time after which the result of a microbiological urine test with an antibiogram is obtained is 2-3 days. Statistically significantly more often ($p = 0.032$) the correct answer was indicated by the staff from conservative wards (206; 72.28% vs 225; 64.29%). The most common incorrect answer was the term waiting time after one week.

The last element in the field of microbiology of infections and microbiological diagnostics covered strains that are classified as alarm factors. The vast majority of respondents correctly identified methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant *Enterococcus faecium* (VRE), and *Escherichia coli* producing ESBL beta-lactamase (223; 78.25% vs 265; 75.71%, $p = 0.452$). The erroneous indication was to select only one strain: methicillin-resistant *Staphylococcus aureus* (MRSA) (Table 9).

The third area, i.e., the last one, covered various ways to prevent nosocomial infections and contained 8 questions.

In the case of the question regarding perioperative antibiotic prophylaxis, the correct answer is that it is a short (usually one dose) administration of an antibiotic (usually cefazolin) just before the procedure in a contaminated clean field or a clean field with a high risk of infection. This was statistically significantly more often ($p = 0.028$) given by nurses and nurses working in surgical wards (99; 28.29% vs 59; 20.70%). Every 7th respondent incorrectly indicated the answer as a short (usually one dose) administration of an antibiotic (usually cefazolin) just before each surgical procedure.

According to the respondents, the correct management of a patient in whom the *Klebsiella pneumoniae* NDM strain was detected in a rectal swab taken at admission to the hospital as part of screening tests is to isolate the patient until the end of the hospital stay in a separate room or cohort with patients who have been diagnosed with the same microorganism; therefore, antibiotic therapy should not be implemented. The frequency of correct indications in both study groups (106; 37.19% vs 108; 30.88%) was statistically insignificantly differentiated ($p = 0.093$). The most frequently incorrectly indicated answer was treatment of the patient with an antibiotic in accordance with the antibiogram and isolation or cohort until the end of antibiotic therapy. Appropriate management of a patient diagnosed with the *Klebsiella pneumoniae* NDM strain is important due to the fact that this bacterium is resistant to most available antibiotics and spreads very easily in the hospital environment.

TABLE 8: Area I: basic concepts of nosocomial infections.

Components of the area I/type of response	Together (n = 635; %)	Conservation ward (n = 285; %)	Treatment department (n = 350; %)	p value*
A nosocomial infection is considered to be any infection that was not in the incubation phase at the time of admission to the hospital, and the symptoms appeared 48–72 hours after admission to the hospital or after discharge from the hospital within a period not longer than the longest incubation period				
Correct	468 (73.70)	228 (80.00)	240 (68.57)	0.001**
Incorrect	167 (26.30)	57 (20.00)	110 (31.43)	
The implementation and operation of a system for preventing and combating nosocomial infections is mandatory for all hospitals, imposed by law				
Correct	593 (93.39)	278 (97.54)	315 (90.00)	0.001**
Incorrect	42 (6.61)	7 (2.46)	35 (10.00)	
The most common clinical form of nosocomial infections is urinary tract infection				
Correct	321 (50.55)	152 (53.33)	169 (48.29)	0.206
Incorrect	314 (49.45)	133 (46.67)	181 (51.71)	
Endogenous infections are caused by microorganisms from the patient's own physiological flora (natural microbiota)				
Correct	438 (68.98)	207 (72.63)	231 (66.00)	0.072
Incorrect	197 (31.02)	78 (27.37)	119 (34.00)	
The use of an antibiotic selected on the basis of an antibiogram is a targeted therapy				
Correct	595 (93.70)	269 (94.39)	326 (93.14)	0.521
Incorrect	40 (6.30)	16 (5.61)	24 (6.86)	
A potential source of infection with HBV, HCV and HIV viruses is blood and any biological material containing blood and semen, pre-ejaculation, and vaginal secretion				
Correct	551 (86.77)	251 (88.07)	300 (85.71)	0.383
Incorrect	84 (13.23)	34 (11.93)	50 (14.29)	

*Test χ^2 ; **p < α ; $\alpha = 0.05$ statistical significance was found.

TABLE 9: Area II: microbiology of infections, including issues related to microbiological diagnostics.

Components of area II/type of response	Together (n = 635; %)	Conservation ward (n = 285; %)	Treatment department (n = 350; %)	p value*
Microorganisms that are the most common etiological agents of nosocomial infections (generally for the entire hospital) are <i>Staphylococcus aureus</i> , <i>Escherichia coli</i> , <i>Pseudomonas aeruginosa</i>				
Correct	461 (72.60)	218 (76.49)	243 (69.43)	0.048**
Incorrect	174 (27.40)	67 (23.51)	107 (30.57)	
The microorganism that is the most common cause of nosocomial diarrhea in adults is <i>Clostridioides difficile</i>				
Correct	538 (84.72)	247 (86.67)	291 (83.14)	0.220
Incorrect	97 (15.28)	38 (13.33)	59 (16.86)	
Nosocomial staphylococcal infections are most often transmitted by the hands of medical personnel				
Correct	438 (68.98)	202 (70.88)	236 (67.43)	0.350
Incorrect	197 (31.02)	83 (29.12)	114 (32.57)	
If sepsis is suspected in a patient with a central venous line, blood should be collected from the central line and 2 separate peripheral lines for microbiological testing				
Correct	303 (47.72)	131 (45.96)	172 (49.14)	0.425
Incorrect	332 (52.28)	154 (54.04)	178 (50.88)	
The result of a microbiological urine test with an antibiogram is obtained after 2-3 days				
Correct	431 (67.87)	206 (72.28)	225 (64.29)	0.032**
Incorrect	204 (32.13)	79 (27.72)	125 (35.71)	
The alarming agents (microorganisms) are methicillin-resistant <i>Staphylococcus aureus</i> (MRSA), <i>Escherichia coli</i> producing ESBL beta-lactamase, and vancomycin-resistant <i>Enterococcus faecium</i> (VRE)				
Correct	488 (76.85)	223 (78.25)	265 (75.71)	0.452
Incorrect	147 (23.15)	62 (21.75)	85 (24.29)	

*Test χ^2 ; **p < α ; $\alpha = 0.05$ statistical significance was found.

With the exception of contact with patients infected with *Clostridioides difficile*, the recommended method of hand hygiene during nursing procedures is hand disinfection using an alcohol-based hand rub. The vast majority of respondents correctly indicated this answer (207; 72.63% vs 256; 73.14%). The most frequently and incorrectly chosen

answer was that if the hands are visually clean, then only hand disinfection using an alcohol-based agent, and washing and subsequent disinfection only when the hands are dirty.

When asked when nonsterile disposable gloves should be used, the correct answer was that during contact with body fluids, excretions, and secretions of the patient and during all

activities with an isolated patient who is colonized/infected with an alert microorganism, this ($p = 0.376$) was indicated by the subjects from the conservative and surgical wards (232; 81.40% vs 275; 78.57%). Incorrectly, the most common response was to use nonsterile disposable gloves only when in contact with body fluids, excretions, and secretions of the patient.

Statistically significantly more often ($p = 0.014$) the respondents from the medical wards (176; 61.75% vs 182; 52.00%) correctly identified the personal protective equipment that should be provided to the nursing staff performing activities with a patient covered by air-dust isolation (gloves, protective apron, filtering half-mask). The most frequently selected incorrect answer was gloves, a protective gown, and surgical mask.

Containers intended for medical waste with sharp ends or edges should be replaced when filled to a maximum of 2/3 of the volume, but at least once every 2-3 days. This answer was correctly indicated by the majority of respondents (235; 82.48% vs 287; 82.00%, $p = 0.881$). The incorrectly selected answer was to replace the containers after filling up to 2/3 of their volume, regardless of the time of their use.

When asked how long an alcohol agent should remain on the skin in order to properly disinfect the patient's skin before taking blood for laboratory tests, the nursing staff correctly answered that until it dries or according to the manufacturer's information on the preparation's packaging (228; 80.00% vs 292; 83.43%, $p = 0.264$). The most frequently incorrectly indicated answer was about 10 seconds.

The last question in this area concerned the correct procedure after a needle stick that had previously been used for intravenous injection. The skin should be washed with plenty of lukewarm water and soap, do not squeeze the wound; do not stop bleeding; do not use alcohol-based disinfectants immediately after a cut or puncture; put on a sterile dressing; and report the case of occupational exposure in the workplace. This answer was indicated as correct by the majority of respondents in both groups (267; 93.68% vs. 317; 90.57%). The most frequently incorrectly indicated answer was to stop bleeding immediately after a cut or needle stick, not to use alcohol-based disinfectants, to apply a sterile dressing, and to report a case of occupational exposure in the workplace (Table 10).

4. Discussion

Healthcare-associated infections are a global problem and a major threat to the safety, health, and lives of patients [20]. Reducing the number of nosocomial infections is possible thanks to rigorous adherence to medical procedures as well as consolidating and updating the knowledge of medical staff in the fields of epidemiology, etiology, transmission routes, and, above all, methods of infection prevention. One of the most effective procedures to prevent the spread of infection, both in hospitals and in everyday life is hand hygiene [21]. However, despite the fact that it is a simple procedure, the theoretical and practical knowledge among medical personnel, including nursing staff, is not always satisfactory. Therefore, topics related to hand hygiene should be

a permanent part of health education, not only for medical personnel but also for patients [22]. The importance of education as an important element of infection prevention is emphasized in many studies. The problem should be approached multidimensionally, and the increasing frequency of infections among hospitalized patients must be accompanied by increasing the awareness of medical staff and continuous training in this area [23]. The obtained research results can be easily transferred to the entire region of Poland due to the fact that Kielce is the capital of the Świętokrzyskie Voivodeship, where there are representative hospitals from every level of reference, which can undoubtedly be applied to other centers such as Łódź or Warsaw.

4.1. Sociodemographic Factors. The study showed that the level of knowledge about nosocomial infections is influenced by the education, specialization, and age of the surveyed nurses. Similar results were obtained by the authors of a study conducted in Zhejiang Province, China, in which doctors and nurses working in neonatal intensive care units took part, and the subject of the study was their knowledge and attitudes in the field of prevention and control of nosocomial infections caused by multidrug-resistant organisms. The knowledge of the surveyed people was correlated with gender, education, referral status of the hospital, and additionally with regular supervision and training [24]. A study conducted among nurses in India also showed a statistically significant relationship between infection control knowledge, seniority, and the place of work of nurses [25]. On the other hand, Turkish research, which assessed the impact of various factors on the level of knowledge in the field of hand hygiene before and after the training, did not show a statistically significant effect of seniority on the knowledge of this issue but showed a statistically significant relationship between the increase in knowledge after the training and variables such as marital status, gender, and type of ward [26]. In an interesting study conducted among nonmedical staff from various hospitals in Iran, a statistically significant correlation was obtained between seniority, type of hospital, and knowledge and attitudes regarding the control of nosocomial infections [27]. The work of authors from Uganda, evaluating the knowledge of representatives of various medical professions about the resistance of microorganisms to antibiotics and rational antibiotic therapy, revealed statistically significant differences between knowledge and practice. Nurses had lower knowledge compared to doctors and pharmacists [28]. Another study from India provided knowledge that statistically significant elements that influenced the state of knowledge among nursing staff about the so-called universal precautions are as follows: gender, place of residence, and education [29]. The impact of similar factors (gender, age, and type of employment) on the knowledge of health professionals in the field of healthcare-associated infections was shown by subsequent studies by Chinese authors. In addition, it was shown that people who participated in clinical consultations with infectious disease doctors had greater knowledge [30].

TABLE 10: Area III: ways to prevent nosocomial infections.

Components of area III/type of response	Together ($n = 635$; %)	Conservation ward ($n = 285$; %)	Treatment department ($n = 350$; %)	p value*
Perioperative antibiotic prophylaxis is a short (usually 1 dose) administration of an antibiotic (usually cefazolin) just before surgery in a contaminated clean or clean field with a high risk of infection				
Correct	158 (24.88)	59 (20.70)	99 (28.29)	0.028**
Incorrect	477 (75.12)	226 (79.30)	251 (71.71)	
Proper management of a patient who has a <i>Klebsiella pneumoniae</i> NDM strain detected in a rectal swab taken at hospital admission as part of screening is to isolate the patient until the end of the hospital stay in a separate room or cohort with patients with the same microorganism detected therefore, antibiotic therapy should be implemented				
Correct	214 (33.70)	106 (37.19)	108 (30.88)	0.093
Incorrect	421 (66.30)	179 (62.81)	242 (69.14)	
With the exception of contact with patients infected with <i>Clostridioides difficile</i> , the recommended method of hand decontamination during nursing procedures is hand disinfection using an alcohol-based hand rub				
Correct	463 (72.91)	207 (72.63)	256 (73.14)	0.885
Incorrect	172 (27.09)	78 (27.37)	94 (26.86)	
Nonsterile disposable gloves are used during contact with body fluids, excretions, and secretions of the patient and during all activities with an isolated patient who is colonized/infected with the alarm agent (microorganism)				
Correct	507 (79.84)	232 (81.40)	275 (78.57)	0.376
Incorrect	128 (20.16)	53 (18.60)	75 (21.43)	
When performing activities with a patient remaining in air-dust isolation, the nursing staff should be equipped with the following personal protective equipment: Gloves, protective apron, and filtering half-mask				
Correct	358 (56.38)	176 (61.75)	182 (52.00)	0.014**
Incorrect	277 (43.62)	109 (38.25)	168 (48.00)	
Containers intended for medical waste with sharp ends or edges should be replaced when filled to a maximum of 2/3 of the volume, but at least once every 2-3 days				
Correct	522 (82.20)	235 (82.48)	287 (82.00)	0.881
Incorrect	113 (17.80)	50 (17.54)	63 (18.00)	
In order to properly disinfect the patient's skin before taking blood for laboratory tests, the alcohol agent should remain on the skin until it dries or according to the manufacturer's information on the preparation's packaging				
Correct	520 (81.89)	228 (80.00)	292 (83.43)	0.264
Incorrect	115 (18.11)	57 (20.00)	58 (16.57)	
The correct procedure after a needle injury, which was previously used for intravenous injection, is to wash the skin with plenty of lukewarm water and soap, do not squeeze the wound, do not stop bleeding, do not use alcohol-based disinfectants immediately after a cut or puncture, put on a sterile dressing, report a case of occupational exposure in the workplace				
Correct	584 (91.97)	267 (93.68)	317 (90.57)	0.151
Incorrect	51 (8.03)	18 (6.32)	33 (9.43)	

*Test χ^2 ; ** $p < \alpha$; $\alpha = 0.05$ statistical significance was found.

A study in the United Kingdom assessing knowledge of recommendations for the prevention of methicillin-resistant *Staphylococcus aureus* (MRSA) infection showed the influence of medical specialty on knowledge in this area. In the knowledge-testing survey, the best results were obtained by people specializing in anesthesiology and intensive care, while the weakest people with diagnostic specializations, i.e., radiology, biochemistry, or laboratory medicine. In addition, it was found that the results of epidemiological nurses [8, 31] were higher than those of physicians (8.69 and 6.6 points out of 1, respectively) [32]. Researchers from Ethiopia have shown that although education and professional experience have an impact on medical workers' theoretical knowledge in the field of infections, this knowledge does not translate into appropriate practice. Continuous on- and off-work training and continuous updating of medical procedures related to infection prevention can fill this gap [19].

4.2. Sources of Knowledge. The sources of knowledge that had an impact on the sufficient level of knowledge among the respondents were specialist medical literature and specialist

courses, and the most frequently indicated source of knowledge were internal trainings conducted in the workplace. In Italy, the sources of knowledge indicated by the respondents in the prevention of SSI were guidelines in this area (73.60%) and similar training courses (51.60%) [33]. In Pakistan, the nursing staff mainly gained knowledge from doctors (72.30%), and the other sources of knowledge were training and the Internet (6.90%) [34].

4.3. Time since Last Training. A statistically significant relationship was also found: the shorter the time since the last training, the higher the level of knowledge among nursing staff. Researchers from other countries have reached the same conclusions. In Turkey, nurses who received training in hygienic hand washing increased their knowledge in this area. All nurses had a statistically significantly higher level of knowledge than before the training, and the percentage of correct answers exceeded 90.00% [26]. A study conducted in India on the knowledge, attitudes, and practices of nursing staff in the field of infection control also showed that after the training intervention, knowledge among staff increased

from 9.42 to 12.98 one week after the training, and after a month, it was still high and amounted to 12.18. In addition, it resulted in a reduction in the incidence of urinary tract infections and intravascular catheter-related infections [35]. The same data were provided by a study in Switzerland, where knowledge after a training intervention increased, especially among nurses and medical staff who did not perform managerial functions [36]. In Spain, nurses' knowledge of venous line recommendations also improved with 4 out of 14 instructions following a training program [37]. In a comparative study among Ethiopian and Chinese nurses, more Chinese nurses received training (54.40%) compared to Ethiopian nurses (41.70%). Among Chinese nurses, the vast majority reported regular supervision, monitoring, and monthly training on the prevention of nosocomial infections compared to Ethiopia, where hospitals conducted regular educational programs, but only for new employees [38]. A study in Poland provided other conclusions. The time that has passed since the last training did not significantly affect the level of knowledge, which was at a comparable level among the surveyed nursing staff, while participation in training on nosocomial infections resulted in a higher level of knowledge among the respondents [39]. Kong et al., in their study, checked the knowledge of medical workers about nosocomial infections and hand hygiene in endoscopy rooms before and after the introduction of the PDCA method, which is a modus operandi of continuous improvement. The results confirmed that the knowledge of the surveyed people was statistically significantly higher than in the control group [40]. To sum up, it can be noted that participation in training is a very important factor influencing the level of knowledge among medical staff.

4.4. Areas of Knowledge. In this study, nursing staff had the highest knowledge of basic concepts regarding nosocomial infections (59.21%). Similarly, in Italy, the area in which the level of knowledge was the highest was general issues regarding nosocomial infections [41], while in Iran, most respondents (90.90%) demonstrated the highest knowledge in the field of hand hygiene and medical waste management [27]. Similarly, in the United States, the highest knowledge among nurses was reported in issues related to hand hygiene and handling sharps instruments [42].

4.5. State of Knowledge. Many researchers point out that properly educated and trained nursing staff who follow all prevention rules, such as hand hygiene or isolation, significantly reduce hospital infections. Many studies have also confirmed that it is impossible to replace qualified nursing staff. In intensive care units, when there is an insufficient number of nursing staff or when nurses do not have sufficient knowledge about the prevention and control of nosocomial infections, this significantly increases the incidence of nosocomial infections, complications, and patient deaths. Index SENIC (Study of the Efficacy of Nosocomial Infection Control) found that hospitals reduced nosocomial infections by approximately 32% when their infection

surveillance and control program included four components, two of which involved skilled and knowledgeable staff: at least one full-time infection control specialist for every 250 beds and a trained hospital epidemiologist [43]. Other researchers have also proven the relationship between education and knowledge and the occurrence of nosocomial infections. Urinary tract infections decreased by 9% among patients cared for by nurses with higher education and, therefore, greater knowledge; the same correlation occurred in patients with pneumonia, where this percentage decreased by 6%. Other research conducted by Cho et al. also confirmed this correlation that skilled nurses reducing patients' incidence of pneumonia by 10% [44]. Also, Needleman et al. came to the same conclusions. The association between qualified staff was associated with a shorter hospital stay and a lower incidence of nosocomial urinary tract infections and upper gastrointestinal bleeding. In addition, urinary tract infections decreased among surgical patients [45]. Olatade et al. found a statistically significant relationship between knowledge and their preventive practice against nosocomial infections among health care workers, which is consistent with appropriate expectations [46].

In the study, the general knowledge of nurses and male nurses regarding nosocomial infections was at a sufficient level for the majority of respondents (65.98%). Other data were provided by a Polish study conducted among nursing staff, whose level of knowledge on postexposure prophylaxis and contact-transmitted infections was insufficient [39]. Meanwhile, a sufficient level of knowledge has also been obtained by scientists in other countries. In India, the knowledge of hand hygiene among medical staff was $66.4\% \pm 27.5\%$ [47] and the awareness of nursing staff was 69.25%. The general state of knowledge about nosocomial infections was at a very good level (above 70.00%) [29]. In Pakistan, 65.56% of respondents had adequate knowledge of nosocomial infections [23], while in another study also conducted in the same country, the average result of knowledge was higher and amounted to 79.94 ± 20.67 , and 56.00% of nursing staff had good knowledge [34]. High results were also obtained by researchers in Italy, checking the knowledge of nurses in the prevention and control of nosocomial infections. Among the respondents, 75.80% of people had a sufficient level of knowledge [48]. A similar level of knowledge was obtained by nonmedical staff working in hospitals in Iran in the field of nosocomial infection control. The vast majority of staff (75.00%) had adequate knowledge, and the mean score was 11.2 ± 2.2 (range: 3–15) [27]. Very high results were obtained in the study by Tash et al. where the level of knowledge about hand hygiene practices and the use of personal protective equipment among nurses was as high as 94.40% (85/90) [49]. Nurses in Kosovo had similarly high knowledge; the general level of knowledge on the spread of nosocomial infections was 90.00% [50]. In the United States, nurses also had a good knowledge of nosocomial infection control [42]. In Nepal, however, the level of knowledge was much lower; only 57.10% of the nursing staff had the appropriate knowledge, and the average of the ratings was 27.75 out of 38 [51]. Equally low

knowledge was found in African countries, i.e., Ethiopia, where only 45.50% of nurses had sufficiently good knowledge on the prevention of nosocomial infections [52]. A similar study in Cyprus showed that nurses do not have sufficient knowledge about nosocomial infections in geriatric patients [53]. The same data was provided by another study conducted in Poland. The nursing staff did not have sufficient knowledge about urinary tract infections. The highest scores were obtained by respondents with basic knowledge of urinary tract infections [54]. In Bulgaria, knowledge about the prevention and control of nosocomial infections exists among healthcare professionals but is at a very basic level. Nurses derive their knowledge from their daily work in the hospital [55]. In Australia, the knowledge of nurses has also not reached a high level. The median assessment of ICU staff knowledge of VAP was 6/10 (IQR: 5–7) [56]. In South Korea, the level of hand hygiene knowledge among nursing staff was also low [57]. A low level of knowledge about CRBSI was also found among Jordanian ICU nurses. The average knowledge score was 3.3, and SD was 1.8 (out of 10) [58].

The study showed that the level of knowledge is statistically significantly different and higher in the group of staff working in conservative wards compared to surgical wards, and the median in both groups was 15. Different results were obtained in a study in Italy among nurses working in surgical wards. The nursing staff in surgical wards had a higher level of sufficient knowledge (78.60%) compared to nurses from other wards (73.60%) [48]. Another study conducted in Italy found a similar relationship. Knowledge among the respondents was higher in the people who work in intensive care units [59]. A study in Pakistan also showed that people working in gynecology and surgery, i.e., surgical departments, had higher knowledge than people working in other departments [34]. In Poland, however, the type of ward did not have a statistically significant effect on the general level of knowledge of medical personnel about contact-transmitted infections [60].

In our study, when asked about the correct duration of skin disinfection in a patient before collecting blood for laboratory tests, the respondents correctly indicated that the alcoholic agent should dry or in accordance with the manufacturer's recommendations on the preparation's packaging (81.89%). In Pakistan, the correct duration of hand washing was indicated by fewer staff (73.70%) [61]. A similar study was conducted in Germany, assessing the knowledge and behavior of nurses and nursing managers regarding hand hygiene in nursing homes. The respondents obtained comparable results (79.00%) in the field of effective hand hygiene methods, answering that 30 seconds is the correct time for hand disinfection [62]. In India, significantly fewer people (54.00%) [47] answered the same question correctly. In another study in India, the respondents' knowledge about the appropriate duration of hygienic and surgical hand washing and the sequence of removing personal protective equipment was at a similar level and amounted to 60.00–70.00% [29].

In our study, nursing staff, when asked about the choice of the recommended method of hand decontamination while performing nursing procedures, except for contacts with patients infected with *Clostridioides difficile*, respondents correctly indicated that it was hand disinfection using an alcohol-based agent (72.91%). Yanke et al. in their study focusing on the prevention of *Clostridioides difficile* infections indicated that some employees wrongly believed that alcohol-based hand sanitizer was an effective method of decontaminating hands after leaving the room of a patient infected with this anaerobic bacterium [63]. In Italy, much fewer respondents (28.50%) knew that washing hands with soap and water was the right way to prevent the spread of nosocomial infections with this bacterium [64].

In our study, when asked what most often causes hospital staphylococcal infection, nursing staff indicated that it is in the hands of medical staff (68.98%). In India, when asked about the main route of spread of microorganisms among patients in health facilities, more respondents (88.00%) answered correctly that it is the contaminated hands of medical staff and indicated the hospital environment as the most common source of pathogens responsible for infections associated with the provision of health services (40.9%) [47]. Nurses working in Kuwait (73.60%) [65] and Saudi Arabia (77.80%) also showed higher knowledge in this area, indicating the same answer [66]. Nurses working in Kuwait (68.50%) were able to identify 5 moments of hand hygiene [65], and medical students in Slovakia (67.10%) had sufficient knowledge of observing hand hygiene rules [21]. An interesting study was also conducted among medical and nursing students in Greece, where future nurses (60.40%) had higher knowledge than future doctors (57.20%) about hand hygiene [67]. In Greece, during qualitative interviews, medical staff admitted that they did not have sufficient knowledge, especially regarding hand hygiene, wrongly believing that its main purpose was solely to protect staff [68]. Among Dutch nursing staff, the majority of people stated that they had knowledge of "how to work hygienically" and how to explain to patients the purpose of preventing and controlling nosocomial infections [69]. In the United States, only 45.40% of nurses indicated that they always wash their hands before inserting a urinary catheter [31]. In Italy, the vast majority of respondents (91.00%) believed that they always performed hand antiseptics, both before and after invasive procedures, such as catheterization of the urinary bladder or insertion of a cannula into a peripheral vein [33].

When asking the respondents when to use nonsterile disposable gloves, they most often answered that during contact with the patient's body fluids, excretions, and secretions and when performing all activities with an isolated patient who is colonized with an alarm factor (79.84%). A study in India on hand hygiene knowledge, attitudes, and practices found that respondents were less knowledgeable. The study showed that 59.00% of staff believed that wearing gloves could replace hand washing or disinfection [70]. The same view was held among Dutch nurses in a study conducted by Lescure et al. [71]. In the United States, health care workers interviewed reported that they always wear gloves as

part of standard precautions. In addition, most employees declared that they use gloves in situations where they are not necessary and always perform hand hygiene before putting on gloves [72].

In our study, the majority of nursing staff (91.97%) knew the correct procedure for following a needle stick injury that had previously been administered intravenously. Medical staff in Nepal showed higher knowledge (98.80%), indicating that large amounts of lukewarm water and soap should be used after an incidental injury with a sharp medical instrument [51]. In turn, staff in India had lower knowledge in this area, where 78.00% of respondents [47] and 50.00% of nurses knew what to do in the event of a needle stick injury [73].

When examining the knowledge of nursing staff regarding the time after which sharp-edged medical waste containers should be replaced, our respondents answered that after they were filled to a maximum of 2/3 of their volume, but at least once every 2-3 days (82.20%). Respondents in India showed lower knowledge (70.00%) in the proper management of acute medical waste [29], as well as in Nepal, where only half of the respondents believed that an appropriate system and supervision of medical waste are factors influencing the prevention of infections hospital [51]. In Italy, however, nurses indicated that 21.00% of containers intended for medical waste were filled to more than ¾ of their capacity, both in surgical and medical wards [48].

When asked about the potential sources of HBV, HCV, and HIV infection, our respondents answered that it was blood and any biological material containing blood, as well as semen, pre-ejaculate, and vaginal secretions (86.77%). Health care workers in Georgia [74] had an insufficient level of knowledge regarding the above issue, and in Nigeria, the general knowledge of the subject and postexposure procedures among respondents was very low [75].

When asked about the personal protective equipment that medical personnel should be equipped with in the case of air-dust isolation, our respondents answered that they should have gloves, a protective apron, and a filtering half-mask (56.38%). In Spain, more nurses (90.00%) knew that they should wear a mask and protective glasses when suctioning secretions from the trachea [76]. In Nepal, most nurses reported wearing gloves, a mask, and goggles to protect themselves from blood and body fluids [51]. In Jordan, most respondents had knowledge about isolation precautions, but questions about air and contact isolation were the most difficult, and fewer respondents knew the correct answer (40.70%) [77]. In Nigeria, only 8.00% of staff were able to name the types of isolation, and 17.80% believed that personal protective equipment was necessary for isolation. Also, a small number of people (14.50%) were able to name situations in which such isolation is necessary [78]. In Italy, the vast majority of respondents (93.20%) claimed to use disposable protective equipment on patients with infectious diseases [33].

When asked about the use of antibiotics based on the antibiogram, respondents indicated that it was a targeted therapy (93.70%). A similar study was conducted in the

United States, where fewer nurses (64.20%) were familiar with the terms antibiotics and antimicrobial stewardship [79], and in the study by Greendyke et al., a similar number of staff (62.00%) did not have sufficient knowledge [80]. The issue of antibiotic resistance also caused great difficulty among respondents in Saudi Arabia; only 29.10% of nurses knew the correct definition [81]. In Singapore, as many as 38.60% of nurses admitted that they had no or limited knowledge of antimicrobial management [82].

The nursing staff had a good knowledge of alarm microorganisms that are resistant to one or more classes of antibiotics (76.85%). In the Netherlands, fewer nurses felt they had sufficient knowledge about MDROs and were able to provide answers to patients in this area. The average knowledge score was 4.5 (range 0–10), and 2/3 of the respondents would like to increase their knowledge on this topic [69]. In Greece, among the nursing staff working in the ICU, during the interview, few respondents reported information about infections that develop there, and no nurse mentioned the colonization and spread of MDROs [83].

Nurses had a big problem with giving the correct answer regarding perioperative antibiotic prophylaxis. Only 24.88% of respondents knew that one dose of cefazolin should be administered just before the procedure in a clean contaminated field or in a clean field with a high risk of infection. In Italy, even fewer staff (14.10%) knew the correct duration of antibiotic prophylaxis (<24 hours after surgery) in their department [33].

4.6. Limitations of the Study. A limitation of the study in terms of assessing the differences between the sexes may be the small number of men (only 6%) among the respondents. This is due to the fact that the vast majority of nurses are women. The study may also be limited by the time interval between the beginning of the study and its completion, reflecting the time between the distribution of the questionnaires and their return by the respondents. This may raise doubts as to the independence of the answers provided by the respondents. This fact could affect the credibility of the obtained results. Another weakness of the study is the lack of a test validation of the instrument; only the Cronbach's alpha coefficient was used, which indicated that the tested questionnaire is a reliable and a valid tool. The analysis confirmed its reliability in terms of basic psychometric properties. Reliability is demonstrated by high values of Cronbach's alpha coefficient. All questions and statements included in the questionnaires were understandable to the respondents. As a process, validation involves collecting and analyzing data to assess the accuracy of an instrument. There are numerous statistical tests and measures to assess the validity of quantitative instruments, which generally involve pilot testing. Another limitation is the lack of a pilot test of the instrument which should be carried out on a small number of people in order to verify whether the selected methods, techniques, and tools are appropriate for the studied group.

5. Implications for Nursing Management

Nosocomial infections are an integral part of the provision of health services, so it is important to know how to minimize the risk of infections. Particular attention should be paid to the continuous, frequent, and regular training of nurses in the field of nosocomial infections, because the knowledge of nursing staff is insufficient. The acquired specialized knowledge must be translated into the everyday preventive behaviors of nurses and also try to supervise and verify nurses' behavior. Knowledge must be followed by specific preventive behaviors. It is advisable to develop procedures and research tools in the health care system that would be helpful both in assessing and acquiring knowledge about nosocomial infections.

6. Conclusions

The level of knowledge about nosocomial infections among nursing staff is insufficient. Knowledge is diverse, and its main determinants are specialization, education and age. A sufficient level of knowledge among the respondents is conditioned primarily by the use of specialist literature and participation in specialist courses, which determine both the scope and area of knowledge about nosocomial infections. Nursing staff working in conservative wards are characterized by a higher level of knowledge in the area of basic concepts related to nosocomial infections. The area of knowledge that will be strengthened is the microbiology of infections, including issues related to microbiological diagnostics. Postexposure management and methods of monitoring nosocomial infections are the areas in which the respondents most often would like to deepen their knowledge.

Data Availability

The data used in this study will be available upon request.

Disclosure

The article was based on the doctoral dissertation: "Assessment of the state of knowledge and need to educate nursing staff about nosocomial infections".

Conflicts of Interest

The authors declare that they have no conflicts of interest.

Acknowledgments

The project was financed under the program the Minister of Education and Science called "Regional Initiative of Excellence" in the years 2019–2023, (project no. 024/RID/2018/19), amount of financing 11 999 000,00 PLN "and project "WINDOW TO THE WORLD - integrated program of the Jan Kochanowski University of Kielce for the development of the Świętokrzyskie region" under the contract (No. POWR.03.05.00-00-ZR24/18) of June 4, 2019 concluded with the National Center for Research and Development

(intermediate body). The project was also cofinanced by the European Union under the European Social Fund [84].

Aim. The aim of this study was to understand the current status of knowledge-attitude-practice of ICU nurses in tertiary care hospitals regarding swallowing disorders after extubation of tracheally intubated patients and to analyse the influencing factors. **Design.** A cross-sectional study. **Background.** Most patients admitted to the ICU have an endotracheal tube, which may be the cause of acute and/or chronic problems after extubation. Therefore, training of ICU nurses and early extubation are essential to prevent these problems. **Methods.** A convenience sample of clinical nurses ($n = 627$) was selected from Grade A Hospitals in Northwest, North, and Central China as the study population. Survey instruments included the Questionnaire on ICU Nurses' Knowledge, Attitude, and Practice of Postextubation Swallowing Disorders in Patients with Tracheal Intubation. **Data Sources.** Data were sourced from structured questionnaire responses. **Results.** A total of 647 ICU nurses participated in this survey, with 627 valid questionnaires. The three dimensions of knowledge, attitude, practice, and the total score of the questionnaire on ICU nurses' knowledge, attitude, and practice of postextubation swallowing disorders in patients with tracheal intubation were (6.46 ± 3.09), (7.53 ± 1.69), (4.89 ± 2.00), and (18.88 ± 5.18), respectively. Multiple linear regression analysis showed that the factors affecting the total score of PED among ICU nurses were age, nationality, professional title, job satisfaction, and mode of employment. Gender, age, nationality, and job satisfaction were the factors that influenced the score of knowledge. The influencing factors of attitude score include gender, age, nationality, section, professional title, job satisfaction, and mode of employment. The influencing factors of the score of knowledge include professional title and job satisfaction. **Conclusion.** The current status of ICU nurses' knowledge-attitude-practice regarding postextubation dysphagia in tracheally intubated patients is generally at a moderate to low level, and the level of knowledge-attitude-practice needs to be further improved. **Implications for Nursing Management.** The results of the study showed that the knowledge, attitude, and practice of ICU nurses towards tracheal intubation patients' postextubation dysphagia were in the lower middle level. Therefore, it is necessary to improve the knowledge, attitude, and practice of ICU nurses towards tracheal intubation patients' postextubation dysphagia. This may include, but is not limited to, the development of tools for assessing PED, systematic and professional training, and the development of multidisciplinary collaborative models.

1. Introduction

Tracheal intubation is the most commonly used route for establishing an artificial airway and is mainly used for resuscitation and respiratory support in critically ill patients in the Intensive Care Unit (ICU) [1]. Patients with tracheal intubation are a special group of patients with

postextubation dysphagia (PED) due to the potential for anatomical damage, which can cause oral, pharyngeal, and laryngeal lesions affecting local dynamics and sensitivity, impairing the swallowing protection response and leading to swallowing disorders [2–5]. A current foreign systematic evaluation found a 41.0% incidence of PED in adults with severe disease [6]. Other studies investigating PEDs in

different disease types have shown that the incidence of PEDs ranges from 12.4% to 93.0% [2, 7–10], while studies in China have shown that the incidence of PEDs ranges from 7.1% to 67.2% [11–15]. In addition to having a high incidence, PEDs can have many adverse outcomes. Studies have shown that PED leads to increased risk of aspiration, aspiration pneumonia, delayed oral intake, malnutrition, prolonged ICU stay and total length of stay, increased mortality, etc. [16–18]. PED can persist until discharge and affect prognosis, even taking more than 6 months or years to recover, seriously affecting the efficiency of recovery [7, 19] and increasing the economic burden on the public health system [16].

In the clinical setting, ICU nurses are responsible for observing patients and providing daily care, and their knowledge, attitude, and practice towards PEDs can influence the occurrence and prognosis of PEDs. Studies have shown that ICU nurses can play an important role in managing PEDs and reducing adverse outcomes associated with swallowing [20–22]. Therefore, improving ICU nurses' knowledge, attitude, and practice about PEDs may help to improve the management of PEDs, reduce the impact of risk factors and avoid adverse outcomes, and promote patient recovery [23].

2. Background

Multidisciplinary teams of nurses, doctors, therapists, and speeching-language pathologists (SLPs) are emerging worldwide with effective screening and management processes. Surveys have shown that only 41% of hospitals routinely screen for PEDs and 44% of patients complete a swallowing assessment [24, 25], and less than 50% of hospitals in the USA have developed screening methods for PEDs, with rates of PED assessment varying between hospitals [26]. A review of the literature found that existing studies on the assessment of PEDs have been under-emphasised and that there is a lack of relevant research and guideline norms [27].

In China and abroad, most studies related to PED have focused on investigating its incidence, influencing factors, or exploring the adverse outcomes caused by PED, but no studies have been conducted on ICU nurses' knowledge-attitude-practice regarding PED in tracheally intubated patients. In order to understand the awareness and importance of PEDs among ICU nurses, it is necessary to investigate the current status of their knowledge, attitude, and practice regarding PEDs in tracheally intubated patients and to explore the factors that influence knowledge, attitude, and practice. This will provide a basis for developing targeted training that will help to reduce the incidence of PEDs and adverse outcomes.

3. Methods

3.1. Aim. The aim of this study was to understand the current status of knowledge-attitude-practice of ICU nurses in tertiary care hospitals regarding swallowing disorders after extubation of tracheally intubated patients and to analyse the influencing factors.

3.2. Study Design. A cross-sectional survey design was used.

3.3. Sample and Setting. A convenience sampling method was adopted to select ICU nurses from selected Grade A Hospitals in Northwest, North, and Central China as the study population. The types of ICUs included general ICU and specialized ICU. Inclusion criteria were as follows: (1) those who obtained the nursing practice certificate; (2) ICU staff in service; and (3) informed consent and willingness to cooperate with the survey. Exclusion criteria were as follows: ICU nurses on rotation, refresher course, or internship. Based on the descriptive study sample size, the estimated sample size was calculated as 10–15 times the total number of entries in the questionnaire [28] and increased by 10% to eliminate the effect of the presence of unqualified questionnaires [29], as the finalised questionnaire had a total of 30 entries, i.e., $\text{sample size} = \text{number of entries} \times (10-15) \times (1 + 10\%) = (385-495)$, and finally the above sample size requirements and the composition of ICU nurses in the surveyed hospitals were integrated. Finally, 627 participants were enrolled in the study.

3.4. Instruments. The Questionnaire on ICU Nurses' Knowledge, Attitude, and Practice of Postextubation Swallowing Disorders in Patients with Tracheal Intubation consists of two parts: (i) a questionnaire on general demographic information of ICU nurses; and (ii) a questionnaire on ICU nurses' knowledge, attitude, and practice of postextubation swallowing disorders in patients with tracheal intubation (final questionnaire determined after item analysis and reliability testing), with a total of 30 items. Instrument details are given in supplemental files (available here).

3.4.1. A Questionnaire on General Demographic Information of ICU Nurses. The demographic survey items measured gender, age, nationality, marital status, education, section, years of experience, title, whether they are a manager, satisfaction with their job, mode of employment, and frequency of night shifts.

3.4.2. The ICU Nurses' Knowledge-Attitude-Practice Questionnaire on Postextubation Dysphagia in Patients with Tracheal Intubation. The questionnaire was developed through the construction of an initial pool of questionnaire items, two rounds of Delphi expert correspondence, item analysis, and reliability testing. A total of 300 questionnaires were sent out as reliability and validity tests, and 276 valid questionnaires were finally collected, with a recovery rate of 92.00%. The questionnaire consisted of 30 items in 3 dimensions: knowledge, attitude, and practice. Cronbach's alpha coefficient was 0.901, and the retest reliability was 0.990. The content validity (I-CVI) of each item ranged from 0.88 to 1.00 and the S-CVI/UA was 0.90. No exploratory factor analysis was required, and one common factor was extracted by exploratory factor analysis for the attitude and practice sections, with a cumulative variance contribution of 67.86% and 81.04%, which met the corresponding requirements.

3.5. Data Collection. With the help of the supervisor and relevant staff, the ICU nurse manager and the person in charge of the hospital being surveyed were contacted in advance to explain the content, purpose, and significance of the survey and to obtain cooperation. The survey was conducted using a uniform questionnaire guideline and method of completion and was carried out by the subject team members through paper or online questionnaires. The data were collected in Chinese and translated by the team. Then the English teacher of Lanzhou University was asked to proofread and finally translate the same into English.

3.6. Data Analysis. The data obtained from the research were evaluated using the SPSS 25.0 package program. The measurement data were expressed as mean and standard deviation using independent samples *t*-test or one-way ANOVA; the count data were described by frequency, composition ratio (%), and percentage (%). Pearson correlation analysis was used to explore the relationship between knowledge, attitude, and practice scores. Multiple linear regression analysis was used to analyse the factors influencing ICU nurses' knowledge-attitude-practice towards tracheal intubation patients with PED. In all analyses, $p < 0.05$ was set for significance.

3.7. Ethics Review. The study was reviewed and approved by the Institutional Review Board of Lanzhou University (no: LZUHLXY20200030). Informed consent was obtained from all participants.

4. Results

4.1. Demographic Characteristics. A total of 647 questionnaires were distributed and 627 valid questionnaires were finally returned, with a valid return rate of 96.91%. As shown in Table 1, 79% of the participants were female ($n = 496$), 37% of the nurses were between 26 and 30 years of age ($n = 233$), 69% were unmarried ($n = 435$), and 60% had a Bachelor's degree as their highest level of education ($n = 379$). 53% ($n = 332$) and 47% ($n = 295$) of the nurses were working in the general ICU and specialized ICU, respectively. In addition, 57% of the nurses had worked for 1–5 years ($n = 359$), 63% of the nurses had a junior title ($n = 393$), 20% of the participants were managers ($n = 123$), 19% of the nurses were very satisfied with their job ($n = 118$), 4% were very dissatisfied ($n = 25$), 56% of the nurses were contractual workers ($n = 354$), and 41% of the nurses work 5–8 night shifts a month ($n = 260$) and only 12% do not have to work night shifts ($n = 75$).

4.2. ICU Nurses' Knowledge-Attitude-Practice Level of PED. The results in Tables 2 and 3 show that the total score of knowledge-attitude-practice for PED was (18.88 ± 5.18), which was converted to a standard score of (62.90 ± 17.27). The scores of the three dimensions of knowledge, attitude, and

practice were (6.46 ± 3.09), (7.53 ± 1.69), and (4.89 ± 2.00), which were converted to a standard score of (64.6 ± 30.90), (75.30 ± 16.90), and (48.90 ± 20.00), respectively. Of the 3 dimensions and the total scores, the attitude dimension scores were good at the upper middle level, the knowledge dimension scores and the total scores of knowledge-attitude-practice were at the lower middle level, and the practice dimension scores were only at the poor level.

TABLE 2: ICU nurses' scores on KAP dimensions of PED and total scores ($N=627$).

	Range	Score	Standard score
Knowledge	0~10	6.46 ± 3.09	64.60 ± 30.90
Attitude	2~10	7.53 ± 1.69	75.30 ± 16.90
Practice	2~10	4.89 ± 2.00	48.90 ± 20.00
Total score	4~30	18.88 ± 5.18	62.90 ± 17.27

TABLE 3: Rating of ICU nurses' total PED knowledge-attitude-practice scores and standard scores for the three dimensions ($N=627$).

Level	Knowledge, N (%)	Attitude, N (%)	Practice, N (%)
Good	225 (35.89)	190 (30.30)	31 (4.94)
Medium	191 (30.46)	340 (54.23)	179 (28.55)
Poor	211 (33.65)	97 (15.47)	417 (66.51)

4.3. Perceived Levels of Each Dimension of the Questionnaire.

In the knowledge dimension, nurses had the least knowledge about the incidence of PED (K2, 43%) and the most knowledge about clinical manifestations (K4, 79%). In the attitude dimension, the lowest score is the enthusiasm of learning PED knowledge. In the practice dimension, the scores of those who received PED related training were the lowest, and the scores of those who responded to the department in time when they encountered related problems were the highest. The score range of attitude dimension is 0.71–0.77, and the score range of practice dimension is 0.42–0.55. The results are shown in Tables 4–6.

4.4. *Univariate Analysis of the Scores of Knowledge, Attitude, and Practice and Total Scores against Sociodemographic and Professional Variables.* Statistical differences in the knowledge and attitude scores and total scores were observed in different groups of gender, age, nationality, education, years of work, job satisfaction, and mode of employment ($p < 0.05$). The difference between knowledge score and number of night shifts was statistically significant ($p = 0.047$). The differences between the total score of questionnaire ($p = 0.008$) and attitude scores ($p = 0.003$) and professional title were statistically significant. There were statistically significant differences in attitude scores between their marital ($p = 0.037$) and section ($p < 0.001$). There were statistically significant differences between practice score and nationality, education, professional title, and job satisfaction ($p < 0.05$). More detailed information is given in Table 7.

4.5. *Multiple Linear Regression Analysis.* Multiple linear regression analysis showed that the factors affecting the total score of PED among ICU nurses were age (31–35: $\beta = 0.106$, $p = 0.018$; 36–40: $\beta = 0.199$, $p < 0.001$; >40: $\beta = 0.203$, $p < 0.001$), nationality ($\beta = -0.128$, $p < 0.001$), professional title (intermediate: $\beta = -0.126$, $p = 0.003$; junior: $\beta = -0.220$, $p < 0.001$), job satisfaction (more satisfied: $\beta = -0.235$, $p < 0.001$; fair: $\beta = -0.320$, $p < 0.001$; not very satisfied: $\beta = -0.261$, $p < 0.001$; very dissatisfied: $\beta = -0.259$,

$p < 0.001$), and mode of employment ($\beta = -0.110$, $p = 0.009$). Gender ($\beta = 0.088$, $p = 0.025$), age (31–35: $\beta = 0.104$, $p = 0.028$; 36–40: $\beta = 0.177$, $p < 0.001$; >40: $\beta = 0.169$, $p < 0.001$), nationality ($\beta = -0.150$, $p < 0.001$), and job satisfaction (more satisfied: $\beta = -0.122$, $p = 0.018$; fair: $\beta = -0.220$, $p < 0.001$; not very satisfied: $\beta = -0.153$, $p < 0.001$; very dissatisfied: $\beta = -0.205$, $p < 0.001$) were the factors that influenced the score of knowledge. The influencing factors of attitude score include gender ($\beta = 0.078$, $p = 0.024$), age (31–35: $\beta = 0.210$, $p < 0.001$; 36–40: $\beta = 0.305$, $p < 0.001$; >40: $\beta = 0.369$, $p < 0.001$), nationality ($\beta = -0.237$, $p < 0.001$), section ($\beta = -0.088$, $p = 0.007$), professional title (intermediate: $\beta = -0.208$, $p < 0.001$; junior: $\beta = -0.332$, $p < 0.001$), job satisfaction (more satisfied: $\beta = -0.219$, $p < 0.001$; fair: $\beta = -0.247$, $p < 0.001$; not very satisfied: $\beta = -0.263$, $p < 0.001$; very dissatisfied: $\beta = -0.268$, $p < 0.001$), and mode of employment ($\beta = -0.162$, $p < 0.001$). The influencing factors of the score of practice include professional title ($\beta = -0.107$, $p = 0.007$) and job satisfaction (more satisfied: $\beta = -0.202$, $p < 0.001$; fair: $\beta = -0.261$, $p < 0.001$; not very satisfied: $\beta = -0.244$, $p < 0.001$; very dissatisfied: $\beta = -0.159$, $p < 0.001$). More detailed information is given in Table 8.

5. Discussion

5.1. *ICU Nurses Need to Improve Their Knowledge, Attitude, and Practice of PEDs.* A survey of 627 ICU nurses in some Grade A Hospitals in Gansu Province of China showed that ICU nurses' knowledge, attitude, and practice about PEDs are poor and need to be further improved, especially to regulate their practices.

According to the descriptive statistical analysis, in the knowledge dimension, ICU nurses still do not know the incidence of PED, which may be related to the unclear status of PED research because they do not consult relevant literature, but they have a good grasp of basic knowledge. At the same time, the scores of ICU nurses in the items related to PED bedside assessment methods, surgical methods, and rehabilitation training were relatively low, reflecting that ICU nurses should focus on improving their mastery of PED special expertise. In the attitude dimension, the subjective initiative of ICU nurses to PED independent learning is poor, so it is suggested to take measures such as reward and punishment to promote the initiative of ICU nurses to improve independent learning. In the practice dimension, the frequency of ICU nurses receiving relevant training is low, and the frequency of their feedback-related problems is relatively high, which suggests that the department managers should increase the professional knowledge and skills training about PED and actively take effective measures to solve the PED problems in the nursing process.

5.2. *Factors Influencing ICU Nurses' Knowledge, Attitude, and Practice about PEDs Are Diverse.* The higher the age, the higher the knowledge-attitude-practice score. From the univariate analysis, it was found that ICU nurses aged

A10: management of PED	199 (31.74)	221 (35.25)	114 (18.18)	63 (10.05)	30 (4.78)	0.76 ± 0.23

A7 and A10 are reverse questions, which have been normalised.

≥31 years scored higher than those aged between 20 and 30 years, but as the overall score of knowledge-attitude-practice was at a moderate to low level, it was suggested that nursing managers should give more learning opportunities and training guidance to ICU nurses aged ≥31 years, so that they can give full play to their leading role and guide and supervise young nurses to actively learn, thus creating a good learning atmosphere in the department. This will help to improve their knowledge of PEDs and improve their attitudes. The results of the multivariate analysis found that ICU nurses aged 26–30 years old had no significance in the above scores compared to ICU nurses aged 20–25 years old, which may be related to the smaller age gap and shorter working years. As the ICU is a highly specialized unit, the older ICU nurses had more clinical experience and were better able to anticipate the clinical implications of PED-related treatment and care for patients with extubation than the younger nurses, so they were able to pay some attention to it [30].

The lower the professional title, the higher the knowledge-attitude-practice score. Caring for patients with tracheal intubation and preventing them from developing PEDs is a more specific clinical task, and as most of those with senior and intermediate titles are head nurses or above in management, they have some critical thinking and decision-making power and are responsible for taking control of

the whole, but those with junior titles are more focused on specific clinical tasks in the ICU and have more exposure to PED-related knowledge and clinical practice in their work [31]. Those with senior titles scored lower on the attitude dimension, indicating that they place less emphasis on PEDs.

The higher the level of job satisfaction, the higher the total score and each dimension of knowledge-attitude-practice. Studies have shown that nurses' job satisfaction is related to their physical and mental health status [32, 33]. If they are in a long-term physical and mental subhealthy state, it will not only lead to a decrease in job satisfaction, cause a high turnover rate, and reduce work efficiency but also lead to adverse events and reduce their professional identity of nursing work, thus affecting their work attitude. Unit or hospital managers can improve the job satisfaction of ICU nurses by adopting measures such as creating a supportive nursing work environment, developing a reasonable performance allocation system, and providing appropriate incentives, which will increase motivation and help to urge them to learn about PEDs and improve their attitudes and practices.

Formal ICU nurses scored higher than those employed by other forms of employment. Compared to nurses in other modes of employment, they are likely to have more opportunities for further study and training and are therefore better

able to acquire more PED-related knowledge, have a more positive attitude, apply their knowledge in their daily nursing work, and have a stronger sense of professional identity.

6. Conclusion

This study investigated for the first time the current situation of PED knowledge-attitude-practice of ICU nurses in some tertiary level A hospitals in Gansu Province, analysed the factors affecting their knowledge-attitude-practice level, and, based on the results of the study, proposed methods for improvement, providing a basis and suggestions for better care of PED patients and enabling them to carry out appropriate PED training, which has certain theoretical and practical application value.

However, only ICU nurses in some tertiary hospitals in Gansu Province were surveyed, and the location and hospital level of the selected sample had certain limitations, leading to possible regional bias and selection bias. Therefore, the selection of representative hospitals of different grades across the country to expand the sample size is a future research work.

7. Implications for Nursing Management

The results of the study showed that the knowledge, attitude, and practice of ICU nurses towards tracheal intubation patients' postextubation dysphagia were in the lower middle level. Therefore, it is necessary to improve the knowledge, attitude, and practice of ICU nurses towards tracheal

intubation patients' postextubation dysphagia. This may include, but is not limited to, the development of tools for assessing PED, systematic and professional training, and the development of multidisciplinary collaborative models.

Data Availability

All data used to support the findings of this study are included within the article.

Conflicts of Interest

The authors declare that they have no conflicts of interest.

Introduction. During the COVID-19 pandemic, there was a need to promote the most adequate behaviors. It is essential to know what aspects were implemented and what needs to be re-enforced. **Objectives.** (a) To identify the knowledge and behaviors related with preventive measures, lifestyle habits, sources of information, vaccination, and emotions generated and coping strategies and (b) to explore the personal experiences with respect to the knowledge, attitudes, and practices when facing COVID-19. **Design.** A convergent mixed method design. **Setting and Participants.** This study was conducted in the Segrià region (Catalonia, Spain) during the months of January and February 2022, with individuals 18 years old or older. **Methods.** Based on variables proposed by the WHO and a bibliographic review, an ad hoc electronic survey was utilized for the quantitative part, analyzed through frequency distribution or central tendency and dispersion measurements. For the qualitative part, two focus groups were analyzed through content analysis. **Results.** The participants (n QUAN = 1,559; n QUAL = 19) were aware about and applied the prevention measures, but when delving into it, deficiencies were detected especially when referring to hand-washing; lifestyles remained healthy; the population trusted the information from professionals (78.8%), but excess of information led to saturation; protection (75.3%) and herd immunity (47.2%) were recognized with vaccination; and the psychological impact (69.5%) was buffered with the activation of positive coping measures (99.1%), although it was maintained in more than half of them. **Conclusions.** This study showed that prevention measures must be re-enforced, especially hand-washing. Another revealing aspect was psychological impact, which, although coping measures were utilized, was maintained for another two years in most of them. This evidences the need for an intervention centered on this to guarantee the mental health of the population. **Implications for Nursing Management.** The detection of the current needs of the population provides the information necessary for the design of an adapted intervention and for promoting health education programs to address COVID-19 or other future health situations.

1. Introduction

In March, 2020, the World Health Organization (WHO) defined COVID-19 as a global pandemic [1]. This pandemic led to an unprecedented situation, unleashing an important crisis in public health. The outbreak of the virus was a worldwide health threat with consequences at different levels [2]. Faced with this situation, a need arose to rapidly and constantly

interact with society to provide information about course of COVID-19 and about the protection or treatment measures at each stage [3]. In this sense, the available evidence showed how high levels of knowledge about COVID-19 were associated with a positive attitude and correct behaviors [4]. On the contrary, individuals with low levels of knowledge had a lower probability of having the adequate attitudes and preventive behaviors [5].

Health Education (HE) is a useful tool for guaranteeing an adequate level of health-related knowledge, as it promotes behaviors that favor the health of the general population [6]. Also, HE provides the necessary tools for acquiring critical thinking skills, to be able to decide on health matters. Nevertheless, HE goes beyond increasing one's knowledge about personal health-related behaviors, as its intention is to also deploy skills and actions to address determinant social, economic, and environmental factors of health [7]. The first phases of an HE program are the analysis of reality and the detection of needs. Once these are identified, they will allow the design of an intervention adapted to current reality and needs [8].

Thus, after more than two years of pandemic and as evidence was not found in our context, a decision was made to assess the consequences of the pandemic and to delve into the knowledge acquired and that which must be re-enforced. Given that knowledge about this disease has evolved since the start of the pandemic, with the development of specific measures of virus response and containment that are adapted to the WHO guidelines [9]. To provide some context to the situation, at the start of 2022, Catalonia (Spain) was recovering from the seventh wave, and the most dominant variant of SARS-CoV-2 was Omicron, characterized by its fast propagation [10]. According to the Health Ministry of Spain [11], on February 15th, 2022, there was a total of 41,007,734 people with at least one dose of the vaccine (86.6% of the Spanish population), and a total of 38,385,465 with the full vaccination (81.0%).

Given the reasons described above and starting with the following research question—What behaviors were adopted by the general population two years after the COVID-19 pandemic?—the general research objective was to analyze the knowledge, attitudes, and practices associated with COVID-19. More specifically, the secondary objectives of the present study were the following: (a) to identify the knowledge and behaviors related with preventive measures, lifestyle habits, sources of information, vaccination, and the emotions created and coping strategies and (b) to explore the personal experiences related with knowledge, attitudes, and practices associated with COVID-19. This analysis will provide the information necessary to address the lack of knowledge, erroneous ideas, or practices, to therefore modify preventive or health awareness programs [12]. It is indispensable for the general population to integrate this information, so that everyone is able to freely, voluntarily, and rationally make health-related decisions [13].

2. Materials and Methods

2.1. Study Design. The present study is part of the project entitled: *Science-Based Education and Communication to Fight COVID-19 and Future Pandemics* (IlerCOVID). This project is centered on strengthening scientific knowledge about COVID-19 and pandemics in the Segrià region (Catalonia, Spain). It combines four work areas: artificial intelligence, plant biotechnology and neuroCovid, education, and communication. The present study corresponds to the working area of education and includes a HE program

based on a brief group education intervention, more specifically on the development of the first phases of the program, in which the knowledge of the population is explored and detailed.

Thus, in line with the objectives described, a study is presented with a convergent mixed methods design [14]. More specifically, the quantitative (QUAN) and qualitative (QUAL) data were collected during a similar amount of time. Afterwards, the two types of data were analyzed separately and in parallel. Lastly, the data were combined, which allowed for a more in-depth exploration of the phenomenon under study.

2.2. Context and Participants. The study population in the QUAN part corresponded to individuals 18 years old or older from the different municipalities of the Segrià region. More specifically, according to the data from the Catalanian Statistics Institute, dated January 1, 2021, the total population in the 38 municipalities was 211,609 individuals, of which 81.8% were 18 years old or older (173,010 individuals). The sample size was calculated to estimate a proportion, and given that many parameters were to be assessed, a maximum indetermination ($p = 0.50$) position was selected, with a confidence interval of 95%, and assuming a sampling error (ϵ) of 3%, which resulted in a sample of 1,062 individuals.

As for the QUAL part, a purposeful sampling method was utilized [15]. The sampling strategy used maximum variation to achieve sample heterogeneity, based on two aspects: (1) willingness to participate and (2) representation of the general population without excluding any socio-demographic category. Thus, the inclusion criteria were broad in order to obtain diverse and rich information on the phenomenon studied: people older than 18 years, from different age groups, without specifying education or limits according to economic level, and who resided in the Segrià region during the COVID-19 pandemic. As for the exclusion criteria, these were individuals with communication problems, with a language barrier with Catalan or Spanish, or with cognitive problems.

2.3. Instruments and Data Collection. For the collection of QUAN data, an ad hoc electronic survey was designed. The variables proposed by the WHO Regional Office for Europe [16] were used. These variables were measured using validated questions or adapted validated questions. The questionnaire as a whole was validated through the six rounds of data collection in Germany. It was translated following the recommendation from the guide itself. Nevertheless, the answers to some of the questions had to be adapted to the country where the study took place, as many of the measures and actions related to COVID-19 were dependent on the national context. Thus, a bibliographic review was performed to adapt the questions to the specific geographical context. Ultimately, 34 questions were included, grouped into 6 sections: (1) sociodemographic data (age, sex, and level of education), (2) COVID-19 preventive measures, (3) lifestyle habits, (4) sources of information, (5) vaccination, and (6) emotions generated and coping strategies. Also, the

recommendations on sample sized were followed, as a sample greater than 1000 participants was included. The Pointerpro platform was utilized, and all the city council from each municipality were contacted for the distribution of digital media, during the months of January and February 2022.

In addition, for the collection of the QUAL data, two focus groups were convened in two randomly selected populations in February 2022. Three areas were explored: knowledge, attitudes, and practices (Table 1). The participants were volunteers recruited by the city councils in each municipality through personal contacts and their social networks or dissemination media.

The focus groups met in municipal rooms and were guided by two researchers (JR and CC), an expert senior researcher in QUAL methodology and a novel researcher. These sessions lasted between 90 and 100 minutes. They were audio-recorded for their posterior literal translation. The participants accepted the transcriptions.

2.4. Data Analysis. In first place, for the QUAN data, a descriptive analysis of the sample was performed through frequency distribution measurements or measurements of central tendency and dispersion, as a function of the nature of the variables. The statistical program utilized was Statistical Package of the Social Sciences (SPSS) version 27.

In the QUAL analysis of the data, a series of actions were performed to ensure the criteria of credibility, dependability, and transferability [17, 18]: (1) the participants were selected in heterogeneous manner, which provided rich and varied information; (2) information was provided about the participants and the context; (3) at the start, two researchers (JR and CC) revised the units of meaning, the process of abstraction, condensation, and creation of the categories and the topics independently, to increase credibility, and afterwards, in a joint work session with the entire research team, the thematic areas defined in each analysis were agreed upon and discussed; (4) stopping criteria were defined when no new categories emerged in the last focus group [19]; and (5) lastly, the data collected and results found were compared and contrasted in a final report. The analysis was performed with the Atlas-Ti version 8 software.

2.5. Ethical Approval. The present study was approved by the Drug Research Ethics Committee from the main hospital in the area (CEIC-2593). The electronic survey participants were informed about the voluntary character and anonymity of the survey, and they were explicitly asked to provide their informed consent before answering the survey. The focus group participants were verbally informed by the researchers and signed an informed consent form. All the data were treated with confidentiality and anonymously.

3. Results

The findings from the present study are described in 6 sections (characteristics of the participants, COVID-19 preventive measures, lifestyle habits, sources of information,

vaccination, and emotions generated and coping strategies). The QUAN and QUAL data are combined in these sections. See Table 1 in the Supplementary Material for a detailed summary of the QUAL themes, categories/subcategories, and units of meaning.

3.1. Characteristics of the Participants. In the QUAN part, 1,559 answers were ultimately obtained (46.8% more than the required sample) from individuals living in the Segrià region, aged between 18 and 90 years old, with a mean age of 49.1 years old (SD = 13.4). Women represented 77.4% of the sample, and 51.1% of the participants had a university degree, followed by secondary (40.7%) and primary (8.2%) education.

As for the QUAL part, a total of 19 participants were obtained (9 from Benavent de Segrià and 10 from Corbins). The age range was 18 to 73 years old, with a mean age of 52.6 years (SD = 19.3). More men participated (57.9%) than women, and most of them had primary education (47.4%), followed by secondary (36.8%) and university (15.8%) education.

3.2. COVID-19 Preventive Measures. With respect to the preventive measures, the most recognized by the participants were those related with the use of the face mask (2.3, 2.4, and 2.5), and the least was the option of washing their hands with a hydroalcoholic solution, as shown in Table 2. Only 22.9% identified all the measures that were correct to avoid or reduce COVID-19 infection (* in Table 2).
